MOTION MOUNTAIN

CHRISTOPH SCHILLER

MOTION MOUNTAIN

Preface

> Primum movere, deinde docere.*
>
> Antiquity

The intense curiosity with which small children explore their environment suggests that there is a drive to grasp the way the world works, a 'physics instinct', built into each of us. What would happen if this drive, instead of being stifled during school education, as it usually is, were allowed to thrive in an environment without bounds, reaching from the atoms to the stars? Probably most adolescents would then know more about nature than most senior physics teachers today. And they would be well-prepared to shape their lives. This text tries to provide this possibility to the reader. It acts as a guide in an exploration, free of all limitations, of physics, the *science of motion*. The project is the result of a threefold aim I have pursued since 1990: to present the basics of motion in a way that is simple, up to date and vivid.

In order to be *simple*, the text focuses on concepts, while keeping mathematics to the necessary minimum. Understanding the concepts of physics is given precedence over using formulae in calculations. The whole text is within the reach of an undergraduate. It presents simple summaries of the main domains of physics.

There are three main stages in the physical description of motion. First, there is everyday physics, or classical continuum physics. It is based on the existence of the infinitely small and the infinitely large. In the second stage, each domain of physics is centred around a basic inequality for the main observable. Thus, statistical thermodynamics limits entropy by $S \geqslant k/2$; special relativity limits speeds by $v \leqslant c$; general relativity limits force by $F \leqslant c^4/4G$; quantum theory limits action by $L \geqslant \hbar/2$; and quantum electrodynamics limits change of charge by $\Delta q \geqslant e$. These results, though not so well known, are proved rigorously. It is shown that within each domain, the principal equations follow from the relevant limit. Basing the domains of physics on limit principles allows them to be introduced in a simple, rapid and intuitive way. The third and final stage is the unification of all these limits in a single description of motion. This unusual way of learning physics should reward the curiosity of every reader – whether student or professional.

In order to be *up to date*, the text includes introductions to quantum gravity, string theory and unification. Meanwhile, the standard topics – mechanics, electricity, light, quantum theory, particle physics and general relativity – are enriched by the many gems – both theoretical and empirical – that are scattered throughout the recent scientific literature.

In order to be *vivid*, a text must be challenging, questioning and daring. This text tries to startle the reader as much as possible. Reading a book on general physics should be like going to a magic show. We watch, we are astonished, we do not believe our eyes, we think, and finally – maybe – we understand the trick. When we look at nature, we often have the same experience. The text tries to intensify this by following a simple rule: on each page, there should be at least one surprise or provocation for the reader to think about. Numerous interesting challenges are proposed. Hints or answers to these are given in an appendix.

* 'First move, then teach.' In modern languages, the mentioned type of moving (the heart) is often called *motivating*; both terms go back to the same Latin root.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The strongest surprises are those that seem to contradict everyday experience. Most of the surprises in this text are taken from daily life: in particular, from the things one experiences when climbing a mountain. Observations about trees, stones, the Moon, the sky and people are used wherever possible; complex laboratory experiments are mentioned only where necessary. These surprises are organized so as to lead in a natural way to the most extreme conclusion of all, namely that *continuous space and time do not exist*. The concepts of space and time, useful as they may be in everyday life, are only approximations. Indeed, they turn out to be mental crutches that *hinder* the complete exploration of the world.

Giving full rein to one's curiosity and thought leads to the development of a strong and dependable character. The motto of the text, *die Menschen stärken, die Sachen klären*, a famous statement by Hartmut von Hentig on pedagogy, translates as: 'To clarify things, to fortify people.' Exploring any limit requires courage; and courage is also needed to abandon space and time as tools for the description of the world. Changing habits of thought produces fear, often hidden by anger; but we grow by overcoming our fears. Achieving a description of the world without the use of space and time may be the most beautiful of all adventures of the mind.

Eindhoven and other places, 8 January 2009

Advice for learners

In my experience as a teacher, there was one learning method that never failed to transform unsuccessful pupils into successful ones: if you read a book for study, summarize every section you read, *in your own words, aloud*. If you are unable to do so, read the section again. Repeat this until you can clearly summarize what you read in your own words, aloud. You can do this alone in a room, or with friends, or while walking. If you do this with everything you read, you will reduce your learning and reading time significantly. In addition, you will enjoy learning from good texts much more and hate bad texts much less. Masters of the method can use it even while listening to a lecture, in a low voice, thus avoiding to ever take notes.

Using this book

Text in green, as found in many marginal notes, is a link that can be clicked in a pdf reader. Green links can be bibliographic references, footnotes, cross references to other pages, challenge solutions or URLs of other websites.

Solutions and hints for *challenges* are given at the end of each part. Challenges are classified as research level (r), difficult (d), standard student level (s) and easy (e). Challenges of type r, d or s for which no solution has yet been included in the book are marked (ny).

A request

The text is and will remain free to download from the internet. In exchange, please send me a short email on the following issues:

— What was unclear?
— What story, topic, riddle, picture or movie did you miss?
Challenge 1 s — What should be improved or corrected?

Feedback on the specific points listed on the www.motionmountain.eu/help.html web page is most welcome of all. You can also add feedback directly to www.motionmountain.eu/wiki. On behalf of all other readers, thank you in advance for your input. For a particularly useful contribution you will be mentioned – if you want – in the acknowledgements, receive a reward, or both. But above all, enjoy the reading.

AN APPETIZER

> Die Lösung des Rätsels des Lebens in Raum und Zeit liegt *außerhalb* von Raum und Zeit.*
> Ludwig Wittgenstein, *Tractatus*, 6.4312

What is the most daring and amazing journey we can make in a lifetime? We can travel to remote places, like adventurers, explorers or cosmonauts; we can look at even more distant places, like astronomers; we can visit the past, like historians, archaeologists, evolutionary biologists or geologists; or we can delve deeply into the human interior, like artists or psychologists. All these voyages lead either to other places or to other times. However, we can do better.

The most daring trip of all is not the one leading to the most inaccessible place, but the one leading to where there is no place at all. Such a journey implies leaving the prison of space and time and venturing beyond it, into a domain where there is no position, no present, no future and no past, where we are free of the restrictions imposed by space and time, but also of the mental reassurance that these concepts provide.** In this domain, many new discoveries and new adventures await us. Almost nobody has ever been there; humanity's journey there has so far taken at least 2500 years, and is still not complete.

To venture into this domain, we need to be curious about the essence of travel itself. The essence of travel is *motion*. By exploring motion we will be led to the most fascinating adventures in the universe.

The quest to understand motion can be pursued behind a desk, with a book, some paper and a pen. But to make the adventure more vivid, this text uses the metaphor of a mountain ascent. Every step towards the top corresponds to a step towards higher precision in the description of motion. In addition, with each step the scenery will become more delightful. At the top of the mountain we shall arrive in a domain where 'space' and 'time' are words that have lost all meaning and where the sight of the world's beauty is overwhelming and unforgettable.

Thinking without time or space is difficult but fascinating. In order to get a taste of the issues involved, try to respond to the following questions without referring to either space or time:

Challenge 2 s

— Can you *prove* that two points extremely close to each other always leave room for a third point in between?

* 'The solution of the riddle of life in space and time lies *outside* space and time.' This and other quotes of Ludwig Wittgenstein are from the equally short and famous *Tractatus logico-philosophicus*, written in 1918, first published in 1921; it has now been translated into many other languages.

** Some people might need a clarification: drugs do not provide such experiences.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

— Can you describe the shape of a knot over the telephone?
— Can you explain on the telephone what 'right' and 'left' mean, or what a mirror is?
— Can you make a telephone appointment with a friend without using any terms of time or position, such as 'clock', 'hour', 'place', 'where', 'when', 'at', 'near', 'before', 'after', 'upon', 'under', 'above', 'below'?
— Can you describe the fall of a stone without using the language of space or time?
— Do you know of *any observation at all* that you can describe without concepts from the domains of 'space', 'time' or 'object'?
— Can you explain what time is? And what clocks are?
— Can you imagine a finite history of the universe, but without a 'first instant of time'?
— Can you imagine a domain of nature where matter and vacuum are indistinguishable?
— Have you ever tried to understand why motion exists?

This book explains how to achieve these and other feats, bringing to completion an ancient dream of the human spirit, namely the quest to describe *every* possible aspect of motion.

Why do your shoelaces remain tied? They do so because space has three dimensions. Why not another number? The question has taxed researchers for thousands of years. The answer was only found by studying motion down to its smallest details, and by exploring its limits.

Why do the colours of objects differ? Why does the Sun shine? Why does the Moon not fall out of the sky? Why is the sky dark at night? Why is water liquid but fire not? Why is the universe so big? Why is it that birds can fly but men can't? Why is lightning not straight? Why are atoms neither square, nor the size of cherries? These questions seem to have little in common – but they are related. They are all about motion – about its details and its limitations. Indeed, they all appear, and are answered, in this text. Studying the limits of motion, we discover that when a mirror changes its speed it emits light. We also discover that gravity can be measured with a thermometer. We find that there are more cells in the brain than stars in the galaxy, giving substance to the idea that people have a whole universe in their head. Exploring any detail of motion is already an adventure in itself.

By exploring the properties of motion we will find that, despite appearance, motion never stops. We will find out why the floor cannot fall. We will understand why computers cannot be made arbitrarily fast. We will see that perfect memory cannot exist. We will understand that nothing can be perfectly black. We will learn that every clock has a certain probability of going backwards. We will discover that time does not exist. We will find that all objects in the world are connected. We will learn that matter cannot be distinguished precisely from empty space. We will learn that we are literally made of nothing. We will learn quite a few things about our destiny. And we will understand why the world is the way it is.

The quest to understand motion, together with all its details and all its limits, involves asking and answering three specific questions.

How do things move? Motion is usually defined as an object changing position over time. This seemingly mundane definition actually encompasses general relativity, one of the most amazing descriptions of nature ever imagined. We will find that there is a maximum speed in nature, that space is warped, that it can move, that light does not usually

PHYSICS:
Describing motion with action.
(Unified) theory of motion
Adventures: understanding everything, intense fun with thinking, catching a glimpse of bliss
What are space, time and quantum particles?
General relativity
Adventures: the night sky, measuring curved space, exploring black holes and the universe, space and time
Quantum theory with gravity
Adventures: bouncing neutrons, understanding tree growth
Quantum field theory
Adventures: building accelerators, understanding quarks, stars, bombs and the basis of life, matter, radiation
How do small things move? What are things?
Classical gravity
Adventures: climbing, skiing, space travel, the wonders of astronomy and geology
How do everyday, fast and large things move?
Special relativity
Adventures: understanding time dilation, length contraction and $E=mc^2$
Quantum theory
Adventures: death, sexuality, biology, enjoying art, colours in nature, all high-tech business, medicine, chemistry, evolution
G
c
h, e, k
Galilean physics, electricity and heat
Adventures: sport, music, sailing, cooking, using electricity and computers, understanding the brain and people

FIGURE 1 A complete map of physics: the connections are defined by the speed of light c, the gravitational constant G, the Planck constant h, the Boltzmann constant k and the elementary charge e.

travel in a straight line, and that time is not the same for everybody. We will discover that there is a maximum force of gravity, and that gravity is not an interaction, but rather the change of time with position. We will see how the blackness of the sky at night proves that the universe has a finite age. We will also discover that there is a smallest entropy in nature, which prevents us from knowing everything about a physical system. In addition, we will discover the smallest electrical charge. These and other strange properties and phenomena of motion are summarized in the first three parts of this text, covering mechanics, heat, special relativity, general relativity and electrodynamics. These topics correspond to the four points in the southwest of Figure 1. The question on how things move leads directly to the next question.

What are things? Things are composites of quantons, or quantum particles. Not only

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tangible things, but all interactions and forces – those of the muscles, those that make the Sun burn, those that make the Earth turn, those that determine the differences between attraction, repulsion, friction, creation and annihilation – are made of quantons as well. The growth of trees, the colours of the sky, the burning of fire, the warmth of a human body, the waves of the sea and the mood changes of people are all composed of quantons in motion. This story is told in more detail in the fourth and fifth part of the text, which deal with the foundations and the applications of quantum mechanics. They correspond to the three 'quantum' points of Figure 1. Here we will learn that there is a smallest change in nature. This minimum value of change, given by the quantum of action $\hbar/2$, forces everything in nature to keep changing. In particular, we will learn that it is impossible to completely fill a glass of wine, that eternal life is impossible, and that light can be transformed into matter. If you find this boring, you can read about the substantial dangers involved in buying a can of beans.

Page 1339

The first five parts of this text can be summarized with the help of a few limit principles:

Statistical thermodynamics limits entropy:	$S \geqslant k/2$
Special relativity limits speed:	$v \leqslant c$
General relativity limits force:	$F \leqslant c^4/4G$
Quantum theory limits action (or change):	$L \geqslant \hbar/2$
Quantum electrodynamics quantizes electric charge:	$Q = n\,e$
Quantum asthenodynamics quantizes weak charge.	
Quantum chromodynamics quantizes colour charge.	

In other words, each of the constants of nature $k/2$, c, $c^4/4G$, $\hbar/2$ and e that appear above is a *limit* value. We will discover in each case that the equation of the corresponding domain of physics follows from this limit property. After these results, the path is prepared for the final part of our mountain ascent.

What are space, time and quantons? The recent results of an age-long search are making it possible to start answering this question. One just needs to find a description that explains all limit principles at the same time. This sixth and last part, corresponding to the highest point of Figure 1, is not yet complete, because the necessary research results are not yet available. Nevertheless, some of the intermediate results are striking:

Page 1398

— It is known already that space and time are not continuous; that – to be precise – neither points nor particles exist; and that there is no way to distinguish space from time, nor vacuum from matter, nor matter from radiation.
— It is known already that nature is *not* simply made of particles and vacuum.
— It seems that position, time and particles are aspects of a complex, *extended* entity that is incessantly varying in shape.
— Among the mysteries that should be cleared up in the coming years are the origin of the three dimensions of space, the origin of time and the details of the big bang.
— Current research indicates that motion is an intrinsic property of matter and radiation and that, as soon as we introduce these two concepts in our description of nature,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

motion appears automatically. Indeed, it is impossible *not* to introduce these concepts, because they necessarily appear when we divide nature into parts, an act we cannot avoid because of the mechanisms of our senses and therefore of our thinking.

— Current research also indicates that the final, completely precise, description of nature does not use any form of infinity. We find, step by step, that all infinities appearing in the human description of nature – both the infinitely large and the infinitely small – result from approximations. 'Infinity' turns out to be merely a conceptual convenience that has no place in nature. However, we find that the precise description does not include any finite quantities either!

This sixth and final part of the text thus describes the present state of the search for a unified theory encompassing general relativity and quantum theory. To achieve such a description, the secrets of space, time, matter and forces have to be unravelled. It is a fascinating story, assembled piece by piece by thousands of researchers. At the end of the ascent, at the top of the mountain, the idea of motion will have undergone a complete transformation. Without space and time, the world will look magical, incredibly simple and fascinating: pure beauty.

First Part

Fall, Flow and Heat

In our quest to learn how things move,
the experience of hiking and other motion
leads us to introduce the concepts of
velocity, time, length, mass and temperature,
and to use them to measure change.
We discover how to float in free space,
why we have legs instead of wheels,
why disorder can never be eliminated,
and why one of the most difficult open issues
in science is the flow of water through a tube.

Contents

22 1 Why should we care about motion?

Does motion exist? 23 • How should we talk about motion? 25 • What are the types of motion? 27 • Perception, permanence and change 31 • Does the world need states? 33 • Galilean physics in six interesting statements 34 • Curiosities and fun challenges about motion 35 • Summary on motion 38

39 2 From motion measurement to continuity

What is velocity? 40 • What is time? 45 • Clocks 48 • Why do clocks go clockwise? 49 • Does time flow? 51 • What is space? 52 • Are space and time absolute or relative? 56 • Size – why area exists, but volume does not 57 • What is straight? 61 • A hollow Earth? 61 • Curiosities and fun challenges about everyday space and time 62 • Summary about everyday space and time 72

73 3 How to describe motion – kinematics

Throwing, jumping and shooting 75 • Enjoying vectors 77 • What is rest? What is velocity? 78 • Acceleration 80 • Objects and point particles 83 • Legs and wheels 85 • Curiosities and fun challenges about kinematics 87 • Summary of kinematics 88

89 4 From objects and images to conservation

Motion and contact 90 • What is mass? 91 • Momentum and mass 93 • Is motion eternal? – Conservation of momentum 98 • More conservation – energy 99 • Rotation 102 • Rolling wheels 107 • How do we walk? 108 • Curiosities and fun challenges about conservation 109 • Summary on conservation 115

116 5 From the rotation of the earth to the relativity of motion

How does the Earth rotate? 123 • Does the Earth move? 126 • Is velocity absolute? – The theory of everyday relativity 132 • Is rotation relative? 133 • Curiosities and fun challenges about relativity 134 • Legs or wheels? – Again 139 • Summary on Galilean relativity 141

142 6 Motion due to gravitation

Properties of gravitation 146 • Dynamics – how do things move in various dimensions? 150 • Gravitation in the sky 151 • The Moon 153 • Orbits 155 • Tides 158 • Can light fall? 161 • What is mass? – Again 162 • Curiosities and fun challenges about gravitation 164 • Summary on gravitation 177

178 7 Classical mechanics and the predictability of motion

Should one use force? Power? 178 • Friction and motion 181 • Friction, sport, machines and predictability 181 • Complete states – initial conditions 185 • Do surprises exist? Is the future determined? 186 • Free will 188 • Summary on predictability 189 • Global descriptions of motion 190

194 8 Measuring change with action

The principle of least action 198 • Lagrangians and motion 200 • Why is motion so often bounded? 202 • Curiosities and fun challenges about Lagrangians 205 • Summary on action 208

209 9 Motion and symmetry

Why can we think and talk about the world? 209 • Viewpoints 211 • Symmetries and groups 212 • Representations 213 • Symmetries, motion and Galilean

physics 216 • Reproducibility, conservation and Noether's theorem 219 • Curiosities and fun challenges about symmetry 223 • Parity and time invariance 224 • Summary on symmetry 224

226 10 Simple motions of extended bodies – oscillations and waves
Waves and their motion 228 • Why can we talk to each other? – Huygens' principle 234 • Why is music so beautiful? 236 • Signals 238 • Solitary waves and solitons 240 • Curiosities and fun challenges about waves and extended bodies 243 • Summary on waves and oscillations 249

250 11 Do extended bodies exist? – Limits of continuity
Mountains and fractals 250 • Can a chocolate bar last forever? 250 • The case of Galileo Galilei 252 • How high can animals jump? 254 • Felling trees 254 • The sound of silence 256 • Little hard balls 256 • The motion of fluids 260 • Curiosities and fun challenges about fluids 263 • Curiosities and fun challenges about solids 271 • Summary on extension 276 • What can move in nature? – Flows 276

Chapter 1

WHY SHOULD WE CARE ABOUT MOTION?

> All motion is an illusion.
>
> Zeno of Elea*

Wham! The lightning striking the tree nearby violently disrupts our quiet forest alk and causes our hearts to suddenly beat faster. In the top of the tree e see the fire start and fade again. The gentle wind moving the leaves around us helps to restore the calmness of the place. Nearby, the water in a small river follows its complicated way down the valley, reflecting on its surface the ever-changing shapes of the clouds.

Motion is everywhere: friendly and threatening, terrible and beautiful. It is fundamental to our human existence. We need motion for growing, for learning, for thinking and for enjoying life. We use motion for walking through a forest, for listening to its noises and for talking about all this. Like all animals, we rely on motion to get food and to survive dangers. Like all living beings, we need motion to reproduce, to breathe and to digest. Like all objects, motion keeps us warm.

Motion is the most fundamental observation about nature at large. It turns out that *everything* that happens in the world is some type of motion. There are no exceptions. Motion is such a basic part of our observations that even the origin of the word is lost in the darkness of Indo-European linguistic history. The fascination of motion has always made it a favourite object of curiosity. By the fifth century BCE in ancient Greece, its study had been given a name: *physics*. Ref. 1

Motion is also important to the human condition. What can we know? Where does the world come from? Who are we? Where do we come from? What will we do? What should we do? What will the future bring? What is death? Where does life lead? All these questions are about motion. The study of motion provides answers that are both deep and surprising.

Motion is mysterious. Though found everywhere – in the stars, in the tides, in our eyelids – neither the ancient thinkers nor myriads of others in the 25 centuries since then have been able to shed light on the central mystery: *what is motion?* We shall discover that the standard reply, 'motion is the change of place in time', is inadequate. Just recently an answer has finally been found. This is the story of the way to find it. Ref. 2

Motion is a part of human experience. If we imagine human experience as an island, then destiny, symbolized by the waves of the sea, carried us to its shore. Near the centre of

* Zeno of Elea (*c.* 450 BCE), one of the main exponents of the Eleatic school of philosophy.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

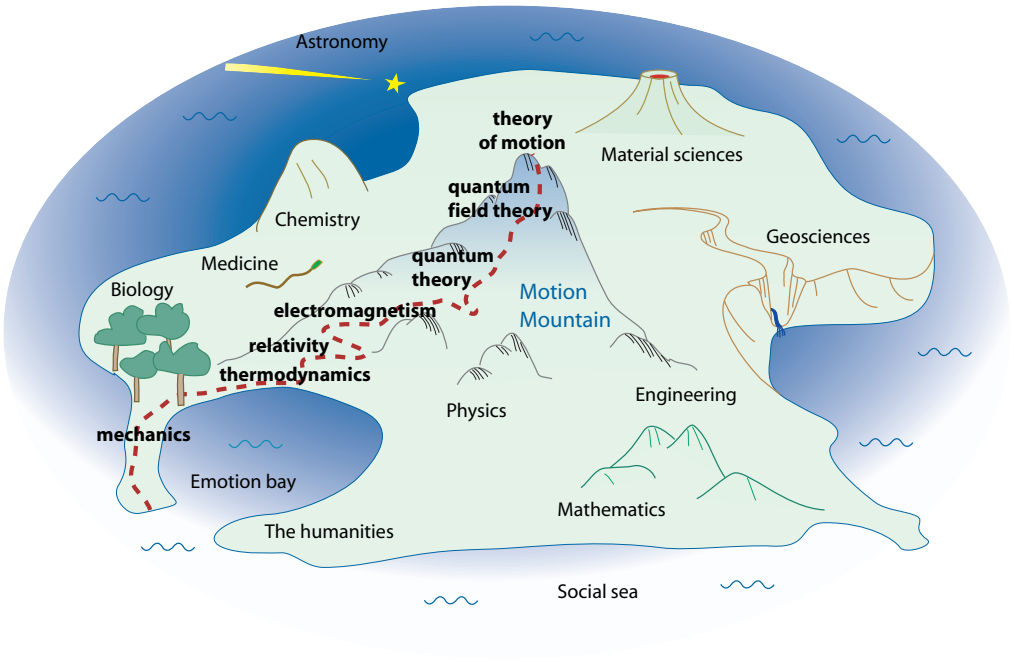

FIGURE 2 Experience Island, with Motion Mountain and the trail to be followed

the island an especially high mountain stands out. From its top we can see over the whole landscape and get an impression of the relationships between all human experiences, in particular between the various examples of motion. This is a guide to the top of what I have called Motion Mountain (see Figure 2; a less artistic but more exact version is given in Figure 1). The hike is one of the most beautiful adventures of the human mind. The first question to ask is:

Does motion exist?

> *Das Rätsel* gibt es nicht. Wenn sich eine Frage überhaupt stellen läßt, so *kann* sie beantwortet werden.*
>
> Ludwig Wittgenstein, *Tractatus*, 6.5

To sharpen the mind for the issue of motion's existence, have a look at Figure 3 or at Ref. 3 Figure 4 and follow the instructions. In all cases the figures seem to rotate. One can experience similar effects if one walks over Italian cobblestone that is laid down in wave patterns or with the many motion illusions by Kitaoka Akiyoshi shown at www.ritsumei. Ref. 4 ac.jp/~akitaoka. How can we make sure that real motion is different from these or other Challenge 3 s similar illusions?

Many scholars simply argued that motion does not exist at all. Their arguments deeply Ref. 5 influenced the investigation of motion. For example, the Greek philosopher Parmenides

* '*The riddle* does not exist. If a question can be put at all, it *can* also be answered.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 3 Illusions of motion: look at the figure on the left and slightly move the page, or look at the white dot at the centre of the figure on the right and move your head back and forward

(born *c.* 515 BCE in Elea, a small town near Naples) argued that since nothing comes from nothing, change cannot exist. He underscored the *permanence* of nature and thus consistently maintained that all change and thus all motion is an illusion. Ref. 6

Heraclitus (*c.* 540 to *c.* 480 BCE) held the opposite view. He expressed it in his famous statement πάντα ῥεῖ 'panta rhei' or 'everything flows'.* He saw change as the essence of nature, in contrast to Parmenides. These two equally famous opinions induced many scholars to investigate in more detail whether in nature there are *conserved* quantities or whether *creation* is possible. We will uncover the answer later on; until then, you might ponder which option you prefer. Challenge 4 s

Parmenides' collaborator Zeno of Elea (born *c.* 500 BCE) argued so intensely against motion that some people still worry about it today. In one of his arguments he claims – in simple language – that it is impossible to slap somebody, since the hand first has to travel halfway to the face, then travel through half the distance that remains, then again so, and so on; the hand therefore should never reach the face. Zeno's argument focuses on the relation between *infinity* and its opposite, finitude, in the description of motion. In modern quantum theory, a similar issue troubles many scientists up to this day. Ref. 7

Zeno also maintained that by looking at a moving object at a *single* instant of time, one cannot maintain that it moves. Zeno argued that at a single instant of time, there is no difference between a moving and a resting body. He then deduced that if there is no difference at a single time, there cannot be a difference for longer times. Zeno therefore questioned whether motion can clearly be distinguished from its opposite, *rest*. Indeed, in the history of physics, thinkers switched back and forward between a positive and a negative answer. It was this very question that led Albert Einstein to the development of general relativity, one of the high points of our journey. In our adventure, we will explore all known differences between motion and rest. Eventually, we will dare to ask whether single instants of time do exist at all. Answering this question is essential for reaching the top of Motion Mountain.

When we explore quantum theory, we will discover that motion is indeed – to a certain extent – an illusion, as Parmenides claimed. More precisely, we will show that motion is observed only due to the limitations of the human condition. We will find that we experience motion only because we evolved on Earth, with a finite size, made of a large but

* Appendix A explains how to read Greek text.

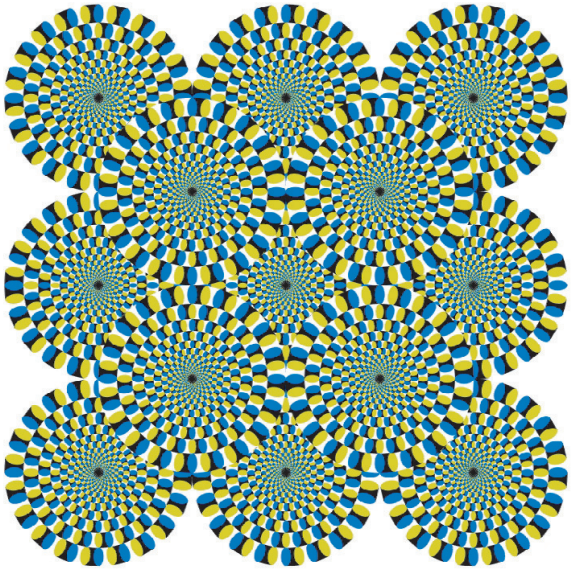

FIGURE 4 Zoom this image to large size or approach it closely in order to enjoy its apparent motion (© Michael Bach after the discovery of Kitaoka Akiyoshi)

finite number of atoms, with a finite but moderate temperature, electrically neutral, large compared with a black hole of our same mass, large compared with our quantum mechanical wavelength, small compared with the universe, with a limited memory, forced by our brain to approximate space and time as continuous entities, and forced by our brain to describe nature as made of different parts. If any one of these conditions were not fulfilled, we would not observe motion; motion, then, would not exist. Each of these results can be uncovered most efficiently if we start with the following question:

How should we talk about motion?

> Je hais le mouvement, qui déplace les lignes,
> Et jamais je ne pleure et jamais je ne ris.
> Charles Baudelaire, *La Beauté*.*

Like any science, the approach of physics is twofold: we advance with *precision* and with *curiosity*. Precision makes meaningful communication possible, and curiosity makes it worthwhile. Be it an eclipse, a beautiful piece of music, or a feat at the Olympic games: the world is full of fascinating examples of motion.**

If you ever find yourself talking about motion, whether to understand it more precisely or more deeply, you are taking steps up Motion Mountain. The examples of Figure 7 make the point. When you fill a bucket with a small amount of water, it does not hang vertically. (Why?) If you continue adding water, it starts to hang vertically at a certain moment. How much water is necessary? When you pull a thread from a reel in the way

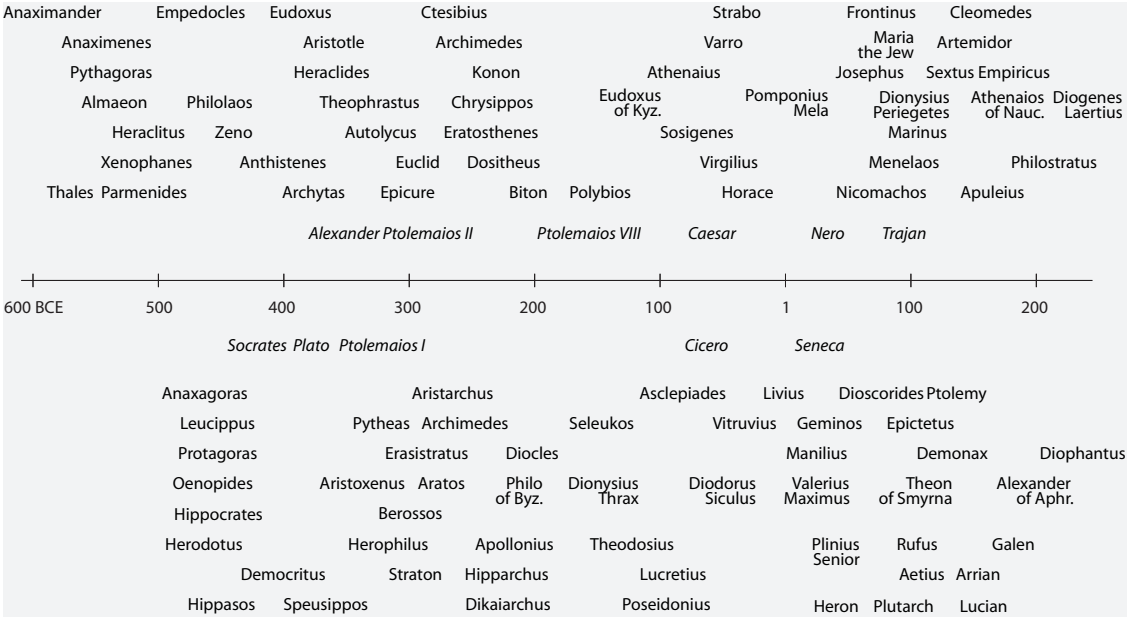

FIGURE 5 A time line of scientific and *political* personalities in antiquity (the last letter of the name is aligned with the year of death)

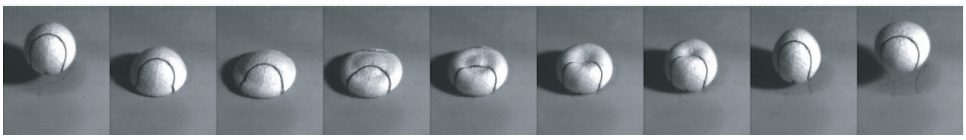

FIGURE 6 An example of how precision of observation can lead to the discovery of new effects: the deformation of a tennis ball during the *c.* 6 ms of a fast bounce (© International Tennis Federation)

shown, the reel will move either forwards or backwards, depending on the angle at which you pull. What is the limiting angle between the two possibilities?

High precision means going into fine details, and being attuned to details actually *increases* the pleasure of the adventure.* The higher we get on Motion Mountain, the further we can see and the more our curiosity is rewarded. The views offered are breath-taking, especially from the very top. The path we will follow – one of the many possible routes – starts from the side of biology and directly enters the forest that lies at the foot of the mountain. Ref. 10

Intense curiosity drives us to go straight to the limits: understanding motion requires exploration of the largest distances, the highest velocities, the smallest particles, the strongest forces and the strangest concepts. Let us begin.

Challenge 6 s * Distrust anybody who wants to talk you *out* of investigating details. He is trying to deceive you. Details are important. Be vigilant also during *this* walk.

connection between gross national product and citizen mobility	

What are the types of motion?

> Every movement is born of a desire for change.
> Antiquity

A good place to obtain a general overview on the types of motion is a large library (see Table 1). The domains in which motion, movements and moves play a role are indeed

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 8 An example of transport, at the Etna (© Marco Fulle)

varied. Already in ancient Greece people had the suspicion that all types of motion, as well as many other types of change, are related. Three categories of change are commonly recognized:

1. Transport. The type of change we call motion in everyday life is material *transport*, such as a person walking, a leaf falling from a tree, or a musical instrument playing. Transport is the change of position or orientation of objects. To a large extent, the behaviour of people also falls into this category.
2. Transformation. Another category of change groups observations such as the dissolution of salt in water, the formation of ice by freezing, the rotting of wood, the cooking of food, the coagulation of blood, and the melting and alloying of metals. These changes of colour, brightness, hardness, temperature and other material properties are all *transformations*. Transformations are changes not visibly connected with transport. To this category, a few ancient thinkers added the emission and absorption of light. In the twentieth century, these two effects were proven to be special cases of transformations, as were the newly discovered appearance and disappearance of matter, as observed in the Sun and in radioactivity. *Mind change*, such as change of mood, of health, of education and of character, is also (mostly) a type of transformation.

Ref. 18

Ref. 19

3. Growth. The last and especially important category of change, *growth*, is observed for animals, plants, bacteria, crystals, mountains, planets, stars and even galaxies. In the nineteenth century, changes in the population of systems, *biological evolution*, and in the twentieth century, changes in the size of the universe, *cosmic evolution*, were added to this category. Traditionally, these phenomena were studied by separate sciences. Independently they all arrived at the conclusion that growth is a combination of transport and transformation. The difference is one of complexity and of time scale.

At the beginnings of modern science during the Renaissance, only the study of transport was seen as the topic of physics. Motion was equated to transport. The other two domains

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 9 Transport, growth and transformation (© Philip Plisson)

were neglected by physicists. Despite this restriction, the field of enquiry remains large, covering a large part of Experience Island. Early scholars differentiated types of transport by their origin. Movements such as those of the legs when walking were classified as *volitional*, because they are controlled by one's will, whereas movements of external objects, such as the fall of a snowflake, which cannot be influenced by will-power, were classified as *passive*. Children are able to make this distinction by about the age of six, and this marks a central step in the development of every human towards a precise description of the environment.* From this distinction stems the historical but now outdated definition of physics as the science of the motion of non-living things.

The advent of machines forced scholars to rethink the distinction between volitional and passive motion. Like living beings, machines are self-moving and thus mimic volitional motion. However, careful observation shows that every part in a machine is moved by another, so their motion is in fact passive. Are living beings also machines? Are human actions examples of passive motion as well? The accumulation of observations in the last 100 years made it clear that volitional movement** indeed has the same physical properties as passive motion in non-living systems. (Of course, from the emotional viewpoint, the differences are important; for example, *grace* can only be ascribed to volitional movements.) A distinction between the two types of motion is thus unnecessary. But since passive and volitional motion have the same properties, through the study of motion of non-living objects we can learn something about the human condition. This

Ref. 20

* Failure to pass this stage completely can result in a person having various strange beliefs, such as believing in the ability to influence roulette balls, as found in compulsive players, or in the ability to move other bodies by thought, as found in numerous otherwise healthy-looking people. An entertaining and informative account of all the deception and self-deception involved in creating and maintaining these beliefs is given by James Randi, *The Faith Healers*, Prometheus Books, 1989. A professional magician, he presents many similar topics in several of his other books. See also his www.randi.org website for more details.

** The word 'movement' is rather modern; it was imported into English from the old French and became popular only at the end of the eighteenth century. It is never used by Shakespeare.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 10 One of the most difficult volitional movements known, performed by Alexander Tsukanov, the first man able to do this: jumping from one ultimate wheel to another (© Moscow State Circus)

is most evident when touching the topics of determinism, causality, probability, infinity, time and sex, to name but a few of the themes we will encounter on the way.

In the nineteenth and twentieth centuries other classically held beliefs about motion fell by the wayside. Extensive observations showed that all transformations and all growth phenomena, including behaviour change and evolution, are also examples of transport. In other words, over 2 000 years of studies have shown that the ancient classification of observations was useless: all change is transport.

In the middle of the twentieth century the study of motion culminated in the experimental confirmation of an even more specific idea, previously articulated in ancient Greece: *every type of change is due to the motion of particles.* It takes time and work to reach this conclusion, which appears only when one relentlessly pursues higher and higher precision in the description of nature. The first five parts of this adventure retrace the path to this result. (Do you agree with it?) Challenge 7 s

The last decade of the twentieth century again completely changed the description of motion: the particle idea turns out to be wrong. This new result, reached through a combination of careful observation and deduction, will be explored in the last part of our adventure. But we still have some way to go before we reach that point, which is near the summit of our journey.

At present, at the beginning of our walk, we simply note that history has shown that classifying the various types of motion is not productive. Only by trying to achieve maximum precision can we hope to arrive at the fundamental properties of motion. Precision, not classification, is the path to follow. As Ernest Rutherford said: 'All science is either physics or stamp collecting.'

To achieve precision in our description of motion, we need to select specific examples of motion and study them fully in detail. It is intuitively obvious that the most precise description is achievable for the *simplest* possible examples. In everyday life, this is the case for the motion of any non-living, solid and rigid body in our environment, such as a stone thrown through the air. Indeed, like all humans, we learned to throw objects long before we learned to walk. Throwing is one of the first physical experiments we per- Ref. 21

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

formed by ourselves.* During our early childhood, by throwing stones, toys and other objects until our parents feared for every piece of the household, we explored the perception and the properties of motion. We do the same here.

> Die Welt ist unabhängig von meinem Willen.**
> Ludwig Wittgenstein, *Tractatus*, 6.373

Perception, permanence and change

> Only wimps study only the general case; real scientists pursue examples.
> Beresford Parlett

Human beings enjoy perceiving. Perception starts before birth, and we continue enjoying it for as long as we can. That is why television, even when devoid of content, is so successful. During our walk through the forest at the foot of Motion Mountain we cannot avoid perceiving. Perception is first of all the ability to *distinguish*. We use the basic mental act of distinguishing in almost every instant of life; for example, during childhood we first learned to distinguish familiar from unfamiliar observations. This is possible in combination with another basic ability, namely the capacity to *memorize* experiences. Memory gives us the ability to experience, to talk and thus to explore nature. Perceiving, classifying and memorizing together form *learning*. Without any one of these three abilities, we could not study motion.

Children rapidly learn to distinguish *permanence* from *variability*. They learn to *recognize* human faces, even though a face never looks exactly the same each time it is seen. From recognition of faces, children extend recognition to all other observations. Recognition works pretty well in everyday life; it is nice to recognize friends, even at night, and even after many beers (not a challenge). The act of recognition thus always uses a form of *generalization*. When we observe, we always have some general idea in our mind. Let us specify the main ones.

Sitting on the grass in a clearing of the forest at the foot of Motion Mountain, surrounded by the trees and the silence typical of such places, a feeling of calmness and tranquillity envelops us. We are thinking about the essence of perception. Suddenly, something moves in the bushes; immediately our eyes turn and our attention focuses. The nerve cells that detect motion are part of the most ancient part of our brain, shared with
Ref. 22 birds and reptiles: the brain stem. Then the cortex, or modern brain, takes over to analyse the type of motion and to identify its origin. Watching the motion across our field of vision, we observe two invariant entities: the fixed landscape and the moving animal. After we recognize the animal as a deer, we relax again.

How did we distinguish between landscape and deer? Perception involves several processes in the eye and in the brain. An essential part for these processes is motion, as is
Ref. 23 best deduced from the flip film shown in the lower left corners of these pages. Each image shows only a rectangle filled with a mathematically random pattern. But when the

* The importance of throwing is also seen from the terms derived from it: in Latin, words like *subject* or 'thrown below', *object* or 'thrown in front', and *interjection* or 'thrown in between'; in Greek, it led to terms like *symbol* or 'thrown together', *problem* or 'thrown forward', *emblem* or 'thrown into', and – last but not least – *devil* or 'thrown through'.

** 'The world is independent of my will.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 11 How do we distinguish a deer from its environment? (© Tony Rodgers)

pages are scanned in rapid succession, you discern a shape – a square – moving against a fixed background. At any given instant, the square cannot be distinguished from the background; there is no visible object at any given instant of time. Nevertheless it is easy to perceive its motion.* Perception experiments such as this one have been performed in many variations. For example, it was found that detecting a moving square against a random background is nothing special to humans; flies have the same ability, as do, in fact, all animals that have eyes.

The flip film in the lower left corner, like many similar experiments, illustrates two central attributes of motion. First, motion is perceived only if an *object* can be distinguished from a *background* or *environment*. Many motion illusions focus on this point.** Second, motion is required to *define* both the object and the environment, and to distinguish them from each other. In fact, the concept of space is – among others – an abstraction of the idea of background. The background is extended; the moving entity is localized. Does this seem boring? It is not; just wait a second.

We call the set of localized aspects that remain invariant or permanent during motion, such as size, shape, colour etc., taken together, a (physical) *object* or a (physical) *body*. We will tighten the definition shortly, since otherwise images would be objects as well. In other words, right from the start we experience motion as a *relative* process; it is perceived in relation and in opposition to the environment. The concept of an object is therefore also a relative concept. But the basic conceptual distinction between localized, isolable objects and the extended environment is not trivial or unimportant. First, it has the appearance of a circular definition. (Do you agree?) This issue will keep us busy later on. Second, we are so used to our ability of isolating local systems from the environment that we take it for granted. However, as we will see in the last part of our walk, this distinc-

Challenge 8 s

Page 317

* The human eye is rather good at detecting motion. For example, the eye can detect motion of a point of light even if the change of angle is smaller than that which can be distinguished in a fixed image. Details of this and similar topics for the other senses are the domain of perception research.

Ref. 11

** The topic of motion perception is full of interesting aspects. An excellent introduction is chapter 6 of the beautiful text by Donald D. Hoffman, *Visual Intelligence – How We Create What We See*, W.W. Norton & Co., 1998. His collection of basic motion illusions can be experienced and explored on the associated aris.ss.uci.edu/cogsci/personnel/hoffman/hoffman.html website.

tion turns out to be logically and experimentally impossible!* Our walk will lead us to discover the reason for this impossibility and its important consequences. Finally, apart from moving entities and the permanent background, we need a third concept, as shown in Table 2.

> Wisdom is one thing: to understand the thought which steers all things through all things.
> Heraclitus of Ephesus

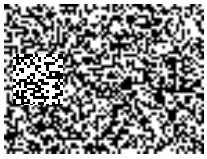
Ref. 24

Does the world need states?

> Das Feste, das Bestehende und der Gegenstand sind Eins. Der Gegenstand ist das Feste, Bestehende; die Konfiguration ist das Wechselnde, Unbeständige.**
> Ludwig Wittgenstein, *Tractatus*, 2.027 – 2.0271

* Contrary to what is often read in popular literature, the distinction *is* possible in quantum theory. It becomes impossible only when quantum theory is unified with general relativity.
** 'The fixed, the existent and the object are one. The object is the fixed, the existent; the configuration is the changing, the variable.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



What distinguishes the various patterns in the lower left corners of this text? In everyday life we would say: the *situation* or *configuration* of the involved entities. The situation somehow describes all those aspects that can differ from case to case. It is customary to call the list of all *variable* aspects of a set of objects their *(physical) state of motion*, or simply their *state*.

The situations in the lower left corners differ first of all in *time*. Time is what makes opposites possible: a child is in a house and the same child is outside the house. Time describes and resolves this type of contradiction. But the state not only distinguishes situations in time: the state contains *all* those aspects of a system (i.e., of a group of objects) that set it apart from all *similar* systems. Two objects can have the same mass, shape, colour, composition and be indistinguishable in all other intrinsic properties; but at least they will differ in their position, or their velocity, or their orientation. The state pinpoints the *individuality* of a physical system,* and allows us to distinguish it from exact copies of itself. Therefore, the state also describes the relation of an object or a system with respect to its environment. Or in short: *the state describes all aspects of a system that depend on the observer.* These properties are not boring – just ponder this: does the universe have a state?

Challenge 10 s

Describing nature as a collection of permanent entities and changing states is the starting point of the study of motion. The various aspects of objects and of their states are called *observables*. All these rough, preliminary definitions will be refined step by step in the following. Using the terms just introduced, we can say that *motion is the change of state of objects*.**

States are required for the description of motion. In order to proceed and to achieve a *complete* description of motion, we thus need a complete description of objects and a complete description of their possible states. The first approach, called Galilean physics, consists in specifying our *everyday* environment as precisely as possible.

Galilean physics in six interesting statements

The study of everyday motion, Galilean physics, is already worthwhile in itself: we will uncover many results that are in contrast with our usual experience. For example, if we recall our own past, we all have experienced how important, delightful or unwelcome *surprises* can be. Nevertheless, the study of everyday motion shows that there are *no* surprises in nature. Motion, and thus the world, is *predictable* or *deterministic*.

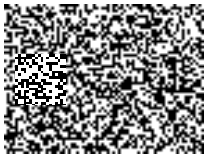
The main surprise is thus that there are no surprises in nature. In fact, we will uncover six aspects of the predictability of everyday motion:

* A *physical system* is a localized entity of investigation. In the classification of Table 2, the term 'physical system' is (almost) the same as 'object' or 'physical body'. Images are usually not counted as physical systems (though radiation is one). Are holes physical systems?

Challenge 9 s

** The exact separation between those aspects belonging to the object and those belonging to the state depends on the precision of observation. For example, the length of a piece of wood is not permanent; wood shrinks and bends with time, due to processes at the molecular level. To be precise, the length of a piece of wood is not an aspect of the object, but an aspect of its state. Precise observations thus *shift* the distinction between the object and its state; the distinction itself does not disappear – at least not for quite a while.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



1. We know that eyes, cameras and measurement apparatus have a finite resolution. All have a smallest distance they can observe. We know that clocks have a smallest time they can measure. Nevertheless, in everyday life all movements, their states, as well as space and time, are *continuous*.
2. We all observe that people, music and many other things in motion stop moving after a while. The study of motion yields the opposite result: motion never stops. In fact, several aspects of motion do not change, but are *conserved*: energy with mass, momentum and angular momentum are conserved in all examples of motion. No exception to conservation has ever been found. In addition, we will discover that conservation implies that motion and its properties are the same at all places and all times: motion is *universal*.
3. We all know that motion differs from rest. Nevertheless, careful study shows that there is no intrinsic difference between the two. Motion and rest depend on the observer. Motion is *relative*. This is the first step towards understanding the theory of relativity.
4. We all observe that many processes happen only in one direction. For example, spilled milk never returns into the container by itself. Nevertheless, the study of motion will show us that all everyday motion is *reversible*. Physicists call this the invariance of everyday motion under motion reversal (or, sloppily, under time reversal).
5. Most of us find scissors difficult to handle with the left hand, have difficulties to write with the other hand, and have grown with a heart on the left side. Nevertheless, our exploration will show that everyday motion is *mirror-invariant*. Mirror processes are always possible in everyday life.
6. We all are astonished by the many observations that the world offers: colours, shapes, sounds, growth, disasters, happiness, friendship, love. The variation, beauty and complexity of nature is amazing. Our study will uncover that all observations can be summarized in a simple way: all motion happens in a way that *minimize change*. Change can be measured, and nature keeps it to a minimum. In other words, despite all appearance, all motion is *simple*. States evolve by minimizing change.

These six aspects are essential in understanding motion in sport, in music, in animals, in machines and among the stars. The first part of our adventure will be an exploration of such movements and in particular, of the mentioned six key properties: continuity, conservation, reversibility, mirror-invariance, relativity and minimization.

Curiosities and fun challenges about motion*

In contrast to most animals, sedentary creatures, like plants or sea anemones, have no legs and cannot move much; for their self-defence, they developed *poisons*. Examples of such plants are the stinging nettle, the tobacco plant, digitalis, belladonna and poppy; poisons include caffeine, nicotine, and curare. Poisons such as these are at the basis of most medicines. Therefore, most medicines exist essentially because plants have no legs.

* *

* Sections entitled 'curiosities' are collections of topics and problems that allow one to check and to expand the usage of concepts already introduced.

Ref. 18 Challenge 27 s Do you dislike formulae? If you do, use the following three-minute method to change the situation. It is worth trying it, as it will make you enjoy this book much more. Life is short; as much of it as possible, like reading this text, should be a pleasure.

1. Close your eyes and recall an experience that was *absolutely marvellous*, a situation when you felt excited, curious and positive.
2. Open your eyes for a second or two and look at page 449 – or any other page that contains many formulae.
3. Then close your eyes again and return to your marvellous experience.
4. Repeat the observation of the formulae and the visualization of your memory – steps 2 and 3 – three more times.

Then leave the memory, look around yourself to get back into the here and now, and test yourself. Look again at page 449. How do you feel about formulae now?

* *

Challenge 28 s In the sixteenth century, Niccolò Tartaglia* proposed the following problem. Three young couples want to cross a river. Only a small boat that can carry two people is available. The men are extremely jealous, and would never leave their brides with another man. How many journeys across the river are necessary?

* *

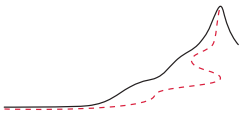
Challenge 29 s Cylinders can be used to roll a flat object over the floor, as shown in Figure 14. The cylinders keep the object plane always at the same distance from the floor. What cross-sections *other* than circular, so-called *curves of constant width*, can a cylinder have to realize the same feat? How many examples can you find? Are objects different than cylinders possible?

Summary on motion

Challenge 30 d Motion is the most fundamental observation in nature. Everyday motion is predictable or deterministic. Predictability is reflected in six aspects of motion: continuity, conservation, reversibility, mirror-invariance, relativity and minimization. Some of these aspects are valid for all motion, and some are valid only for everyday motion. Which ones, and why? We explore this now.

* Niccolò Fontana Tartaglia (1499–1557), important Renaissance mathematician.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 2

FROM MOTION MEASUREMENT TO CONTINUITY

> Physic ist wahrlich das eigentliche Studium des Menschen.*
>
> Georg Christoph Lichtenberg

The simplest description of motion is the one we all, like cats or monkeys, use unconsciously in everyday life: *only one thing can be at a given spot at a given time*. This general description can be separated into three assumptions: matter is *impenetrable* and *moves*, time is made of *instants*, and space is made of *points*. Without these three assumptions (do you agree with them?) it is not possible to define velocity in everyday life. This description of nature is called *Galilean physics*, or sometimes *Newtonian physics*.

Challenge 31 s

Galileo Galilei (1564–1642), Tuscan professor of mathematics, was a founder of modern physics and is famous for advocating the importance of observations as checks of statements about nature. By requiring and performing these checks throughout his life, he was led to continuously increase the accuracy in the description of motion. For example, Galileo studied motion by measuring change of position with a self-constructed stopwatch. His approach changed the speculative description of ancient Greece into the experimental physics of Renaissance Italy.**

The English alchemist, occultist, theologian, physicist and politician Isaac Newton (1643–1727) was one of the first to pursue with vigour the idea that different types of motion have the same properties, and he made important steps in constructing the concepts necessary to demonstrate this idea.***

The explorations by Galileo and his predecessors provided the first clear statements on the properties of speed, space and time.

* 'Physics truly is the proper study of man.' Georg Christoph Lichtenberg (1742–1799) was an important physicist and essayist.

** The best and most informative book on the life of Galileo and his times is by Pietro Redondi (see the section on page 252). Galileo was born in the year the pencil was invented. Before his time, it was impossible to do paper and pencil calculations. For the curious, the www.mpiwg-berlin.mpg.de website allows you to read an original manuscript by Galileo.

*** Newton was born a year after Galileo died. Newton's other hobby, as master of the Mint, was to supervise personally the hanging of counterfeiters. About Newton's infatuation with alchemy, see the books by Dobbs. Among others, Newton believed himself to be chosen by god; he took his Latin name, *Isaacus Neuutonus*, and formed the anagram *Jeova sanctus unus*. About Newton and his importance for classical mechanics, see the text by Clifford Truesdell.

What is velocity?

> There is nothing else like it.
>
> Jochen Rindt*

Velocity fascinates. To physicists, not only car races are interesting, but any moving entity is. Therefore they first measure as many examples as possible. A selection is given in Table 3. The units and prefixes used are explained in detail in Appendix C.

Everyday life teaches us a lot about motion: objects can overtake each other, and they can move in different directions. We also observe that velocities can be added or changed smoothly. The precise list of these properties, as given in Table 4, is summarized by mathematicians in a special term; they say that velocities form a *Euclidean vector space*.** More details about this strange term will be given shortly. For now we just note that in describing nature, mathematical concepts offer the most accurate vehicle.

Page 77

When velocity is assumed to be an Euclidean vector, it is called *Galilean* velocity. Velocity is a profound concept. For example, velocity does not need space and time measurements to be defined. Are you able to find a means of measuring velocities without measuring space and time? If so, you probably want to skip to page 401, jumping 2000

Challenge 33 d

* Jochen Rindt (1942–1970), famous Austrian Formula One racing car driver, speaking about speed.

** It is named after Euclid, or Eukleides, the great Greek mathematician who lived in Alexandria around 300 BCE. Euclid wrote a monumental treatise of geometry, the Στοιχεῖα or *Elements*, which is one of the milestones of human thought. The text presents the whole knowledge on geometry of that time. For the first time, Euclid introduces two approaches that are now in common use: all statements are deduced from a small number of basic 'axioms' and for every statement a 'proof' is given. The book, still in print today, has been the reference geometry text for over 2000 years. On the web, it can be found at aleph0.clarku.edu/

TABLE 3 Some measured velocity values

Observation	Velocity
Growth of deep sea manganese crust	80 am/s
Can you find something slower?	Challenge 32 s
Stalagmite growth	0.3 pm/s
Lichen growth	down to 7 pm/s
Typical motion of continents	10 mm/a = 0.3 nm/s
Human growth during childhood, hair growth	4 nm/s
Tree growth	up to 30 nm/s
Electron drift in metal wire	1 µm/s
Sperm motion	60 to 160 µm/s
Speed of light at Sun's centre	0.1 mm/s
Ketchup motion	1 mm/s
Slowest speed of light measured in matter on Earth Ref. 27	0.3 m/s
Speed of snowflakes	0.5 m/s to 1.5 m/s
Signal speed in human nerve cells Ref. 28	0.5 m/s to 120 m/s
Wind speed at 1 Beaufort (light air)	below 1.5 m/s
Speed of rain drops, depending on radius	2 m/s to 8 m/s
Fastest swimming fish, sailfish (*Istiophorus platypterus*)	22 m/s
Speed sailing record (by windsurfer Finian Maynard)	25.1 m/s
Fastest running animal, cheetah (*Acinonyx jubatus*)	30 m/s
Wind speed at 12 Beaufort (hurricane)	above 33 m/s
Speed of air in throat when sneezing	42 m/s
Fastest throw: a cricket ball thrown with baseball technique while running	50 m/s
Freely falling human, depending on clothing	50 to 90 m/s
Fastest bird, diving *Falco peregrinus*	60 m/s
Fastest badminton serve	70 m/s
Average speed of oxygen molecule in air at room temperature	280 m/s
Speed of sound in dry air at sea level and standard temperature	330 m/s
Cracking whip's end	750 m/s
Speed of a rifle bullet	1 km/s
Speed of crack propagation in breaking silicon	5 km/s
Highest macroscopic speed achieved by man – the *Voyager* satellite	14 km/s
Speed of Earth through universe	370 km/s
Average speed (and peak speed) of lightning tip	600 km/s (50 Mm/s)
Highest macroscopic speed measured in our galaxy Ref. 29	$0.97 \cdot 10^8$ m/s
Speed of electrons inside a colour TV	$1 \cdot 10^8$ m/s
Speed of radio messages in space	299 792 458 m/s
Highest ever measured group velocity of light	$10 \cdot 10^8$ m/s
Speed of light spot from a light tower when passing over the Moon	$2 \cdot 10^9$ m/s
Highest proper velocity ever achieved for electrons by man	$7 \cdot 10^{13}$ m/s
Highest possible velocity for a light spot or shadow	no limit

years of enquiries. If you cannot do so, consider this: whenever we measure a quantity we assume that everybody is able to do so, and that everybody will get the same result. In other words, we define *measurement* as a comparison with a standard. We thus implicitly assume that such a standard exists, i.e., that an example of a 'perfect' velocity can be found. Historically, the study of motion did not investigate this question first, because for many centuries nobody could find such a standard velocity. You are thus in good company.

Some researchers have specialized in the study of the lowest velocities found in nature: they are called geologists. Do not miss the opportunity to walk across a landscape while listening to one of them. Ref. 30

Velocity is not always an easy subject. Physicists like to say, provokingly, that what cannot be measured does not exist. Can one's own velocity in empty interstellar space be measured? Challenge 34 s

How is velocity measured in everyday life? Animals and people estimate their velocity in two ways: by estimating the frequency of their own movements, such as their steps, or by using their eyes, ears, sense of touch or sense of vibration to deduce how their own position changes with respect to the environment. But several animals have additional capabilities: certain snakes can determine speeds with their infrared-sensing organs, others with their magnetic field sensing organs. Still other animals emit sounds that create echoes in order to measure speeds to high precision. The same range of solutions is used by technical devices.

Velocity is of interest to both engineers and evolution. In general, self-propelled systems are faster the larger they are. As an example, Figure 17 shows how this applies to the cruise speed of flying things. In general, cruise speed scales with the sixth root of the weight, as shown by the trend line drawn in the graph. (Can you find out why?) By the way, similar *allometric scaling* relations hold for many other properties of moving systems, as we will see later on. Challenge 35 d

Velocity is a profound subject for an additional reason: we will discover that all seven properties of Table 4 are only approximate; *none* is actually correct. Improved experiments will uncover exceptions for every property of Galilean velocity. The failure of the last three properties of Table 4 will lead us to special and general relativity, the failure of

TABLE 5 Speed measurement devices in biological and engineered systems

Measurement	Device	Range
Own running speed in insects, mammals and humans	leg beat frequency measured with internal clock	0 to 33 m/s
Own car speed	tachymeter attached to wheels	0 to 150 m/s
Predators and hunters measuring prey speed	vision system	0 to 30 m/s
Police measuring car speed	radar or laser gun	0 to 90 m/s
Bat measuring own and prey speed at night	doppler sonar	0 to 20 m/s
Sliding door measuring speed of approaching people	doppler radar	0 to 3 m/s
Own swimming speed in fish and humans	friction and deformation of skin	0 to 30 m/s
Own swimming speed in dolphins and ships	sonar to sea floor	0 to 20 m/s
Diving speed in fish, animals, divers and submarines	pressure change	0 to 5 m/s
Water predators and fishing boats measuring prey speed	sonar	0 to 20 m/s
Own speed relative to Earth in insects	often none (grasshoppers)	n.a.
Own speed relative to Earth in birds	visual system	0 to 60 m/s
Own speed relative to Earth in aeroplanes or rockets	radio goniometry, radar	0 to 8000 m/s
Own speed relative to air in insects and birds	filiform hair deflection, feather deflection	0 to 60 m/s
Own speed relative to air in aeroplanes	Pitot–Prandtl tube	0 to 340 m/s
Wind speed measurement in meteorological stations	thermal, rotating or ultrasound anemometers	0 to 80 m/s
Swallows measuring prey speed	visual system	0 to 20 m/s
Bats measuring prey speed	sonar	0 to 20 m/s
Pilots measuring target speed	radar	0 to 1000 m/s
Any motion on Earth	Global Positioning System, Galileo, Glonass	0 to 100 m/s
Motion of stars	optical Doppler effect	0 to 1000 km/s
Motion of star jets	optical Doppler effect	0 to 200 Mm/s

the middle two to quantum theory and the failure of the first two properties to the unified description of nature. But for now, we'll stick with Galilean velocity, and continue with another Galilean concept derived from it: time.

> Without the concepts *place*, *void* and *time*, change cannot be. [...] It is therefore clear [...] that their investigation has to be carried out, by studying each of them separately.
>
> Aristotle* *Physics*, Book III, part 1.

What is time?

> Time does not exist in itself, but only through the perceived objects, from which the concepts of past, of present and of future ensue.
>
> Lucretius,** *De rerum natura*, lib. 1, v. 460 ss.

In their first years of life, children spend a lot of time throwing objects around. The term 'object' is a Latin word meaning 'that which has been thrown in front.' Developmental psychology has shown experimentally that from this very experience children extract the concepts of time and space. Adult physicists do the same when studying motion at university.

Ref. 21

When we throw a stone through the air, we can define a *sequence* of observations. Our memory and our senses give us this ability. The sense of hearing registers the various sounds during the rise, the fall and the landing of the stone. Our eyes track the location of the stone from one point to the next. All observations have their place in a sequence, with some observations preceding them, some observations simultaneous to them, and still others succeeding them. We say that observations are perceived to happen at various *instants* and we call the sequence of all instants *time*.

* Aristotle (384/3–322), Greek philosopher and scientist.

** Titus Lucretius Carus (*c.* 95 to *c.* 55 BCE), Roman scholar and poet.

TABLE 6 Selected time measurements

Observation	Time
Shortest measurable time	10^{-44} s
Shortest time ever measured	10^{-23} s
Time for light to cross a typical atom	0.1 to 10 as
Shortest laser light pulse produced so far	200 as
Period of caesium ground state hyperfine transition	108.782 775 707 78 ps
Beat of wings of fruit fly	1 ms
Period of pulsar (rotating neutron star) PSR 1913+16	0.059 029 995 271(2) s
Human 'instant'	20 ms
Shortest lifetime of living being	0.3 d
Average length of day 400 million years ago	79 200 s
Average length of day today	86 400.002(1) s
From birth to your 1000 million seconds anniversary	31.7 a
Age of oldest living tree	4600 a
Use of human language	$2 \cdot 10^5$ a
Age of Himalayas	35 to 55 $\cdot 10^6$ a
Age of oldest rocks, found in Isua Belt, Greenland and in Porpoise Cove, Hudson Bay	$3.8 \cdot 10^9$ a
Age of Earth	$4.6 \cdot 10^9$ a
Age of oldest stars	13.7 Ga
Age of most protons in your body	13.7 Ga
Lifetime of tantalum nucleus ^{180m}Ta	10^{15} a
Lifetime of bismuth ^{209}Bi nucleus	$1.9(2) \cdot 10^{19}$ a

An observation that is considered the smallest part of a sequence, i.e., not itself a sequence, is called an *event*. Events are central to the definition of time; in particular, starting or stopping a stopwatch are events. (But do events really exist? Keep this question in the back of your head as we move on.)

Challenge 36 s

Sequential phenomena have an additional property known as stretch, extension or duration. Some measured values are given in Table 6.* *Duration* expresses the idea that sequences *take* time. We say that a sequence takes time to express that other sequences can take place in parallel with it.

How exactly is the concept of time, including sequence and duration, deduced from observations? Many people have looked into this question: astronomers, physicists, watchmakers, psychologists and philosophers. All find that *time is deduced by comparing motions*. Children, beginning at a very young age, develop the concept of 'time' from the comparison of motions in their surroundings. Grown-ups take as a standard the motion of the Sun and call the resulting type of time *local time*. From the Moon they deduce a *lunar calendar*. If they take a particular village clock on a European island they call it the

Ref. 21

* A year is abbreviated a (Latin 'annus').

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

universal time coordinate (UTC), once known as 'Greenwich mean time.'* Astronomers use the movements of the stars and call the result *ephemeris time* (or one of its successors). An observer who uses his personal watch calls the reading his *proper time*; it is often used in the theory of relativity.

Not every movement is a good standard for time. In the year 2000 an Earth rotation did not take 86 400 seconds any more, as it did in the year 1900, but 86 400.002 seconds. Can you deduce in which year your birthday will have shifted by a whole day from the time predicted with 86 400 seconds?

Page 917
Challenge 38 s

All methods for the definition of time are thus based on comparisons of motions. In order to make the concept as precise and as useful as possible, a *standard* reference motion is chosen, and with it a standard sequence and a standard duration is defined. The device that performs this task is called a *clock*. We can thus answer the question of the section title: *time is what we read from a clock*. Note that all definitions of time used in the various branches of physics are equivalent to this one; no 'deeper' or more fundamental definition is possible.** Note that the word 'moment' is indeed derived from the word 'movement'. Language follows physics in this case. Astonishingly, the definition of time just given is final; it will never be changed, not even at the top of Motion Mountain. This is surprising at first sight, because many books have been written on the nature of time. Instead, they should investigate the nature of motion! But this is the aim of our walk anyhow. We are thus set to discover all the secrets of time as a side result of our adventure. Every clock reminds us that in order to understand time, we need to understand motion.

A *clock* is thus a moving system whose position can be read. Of course, a *precise* clock is a system moving as regularly as possible, with as little outside disturbance as possible. Is there a perfect clock in nature? Do clocks exist at all? We will continue to study these questions throughout this work and eventually reach a surprising conclusion. At this point, however, we state a simple intermediate result: since clocks do exist, somehow there is in nature an intrinsic, natural and *ideal* way to measure time. Can you see it?

Challenge 39 s

Time is not only an aspect of observations, it is also a facet of personal experience. Even in our innermost private life, in our thoughts, feelings and dreams, we experience sequences and durations. Children learn to relate this internal experience of time with external observations, and to make use of the sequential property of events in their actions. Studies of the origin of psychological time show that it coincides – apart from its lack of accuracy – with clock time.*** Every living human necessarily uses in his daily life the concept of time as a combination of sequence and duration; this fact has been checked in numerous investigations. For example, the term 'when' exists in all human languages.

Ref. 32

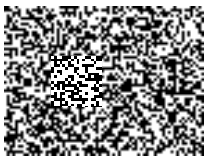
* Official UTC is used to determine the phase of the power grid, phone companies' bit streams and the signal to the GPS system. The latter is used by many navigation systems around the world, especially in ships, aeroplanes and lorries. For more information, see the www.gpsworld.com website. The time-keeping infrastructure is also important for other parts of the modern economy. Can you spot the most important ones?

Challenge 37 s

** The oldest clocks are sundials. The science of making them is called *gnomonics*. An excellent and complete introduction into this somewhat strange world can be found at the www.sundials.co.uk website.

*** The brain contains numerous clocks. The most precise clock for short time intervals, the internal interval timer, is more accurate than often imagined, especially when trained. For time periods between a few tenths of a second, as necessary for music, and a few minutes, humans can achieve accuracies of a few per cent.

Page 1134
Ref. 31



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 7 Properties of Galilean time

Instants of time	Physical property	Mathematical name	Definition
Can be distinguished	distinguishability	element of set	Page 822
Can be put in order	sequence	order	Page 896
Define duration	measurability	metricity	Page 887
Can have vanishing duration	continuity	denseness, completeness	Page 896
Allow durations to be added	additivity	metricity	Page 887
Don't harbour surprises	translation invariance	homogeneity	Page 186
Don't end	infinity	unboundedness	Page 823
Are equal for all observers	absoluteness	uniqueness	

Time is a concept *necessary* to distinguish between observations. In any sequence, we observe that events succeed each other smoothly, apparently without end. In this context, 'smoothly' means that observations that are not too distant tend to be not too different. Yet between two instants, as close as we can observe them, there is always room for other events. Durations, or *time intervals*, measured by different people with different clocks agree in everyday life; moreover, all observers agree on the order of a sequence of events. Time is thus unique in everyday life.

The mentioned properties of everyday time, listed in Table 7, correspond to the precise version of our everyday experience of time. It is called *Galilean time;* all the properties can be expressed simultaneously by describing time with the help of real numbers. In fact, real numbers have been constructed by mathematicians to have exactly the same properties as Galilean time, as explained in the chapter on the brain. Every instant of time can be described by a real number, often abbreviated t, and the duration of a sequence of events is given by the difference between the values for the final and the starting event.

Page 831

When Galileo studied motion in the seventeenth century, there were as yet no stopwatches. He thus had to build one himself, in order to measure times in the range between a fraction and a few seconds. Can you imagine how he did it?

Challenge 40 s

We will have quite some fun with Galilean time in this part of our adventure. However, hundreds of years of close scrutiny have shown that *every single* property of time just listed is approximate, and none is strictly correct. This story is told in the rest of our adventure.

Clocks

A *clock* is a moving system whose position can be read. There are many types of clocks: stopwatches, twelve-hour clocks, sundials, lunar clocks, seasonal clocks, etc. Almost all clock types are also found in plants and animals, as shown in Table 8.

Ref. 33

Interestingly, there is a strict rule in the animal kingdom: large clocks go slow. How this happens, is shown in Figure 20, another example of an *allometric scaling 'law'*.

Ref. 34

Clock makers are experts in producing motion that is as regular as possible. We will discover some of their tricks below. We will also explore, later on, the fundamental limits for the precision of clocks.

Page 145

Why do clocks go clockwise?

Challenge 41 s

"What time is it at the North Pole now?"

All rotational motions in our society, such as athletic races, horse, bicycle or ice skating races, turn anticlockwise. Likewise, every supermarket leads its guests anticlockwise through the hall. Mathematicians call this the positive rotation sense. Why? Most people are right-handed, and the right hand has more freedom at the outside of a circle. Therefore thousands of years ago chariot races in stadia went anticlockwise. As a result, all

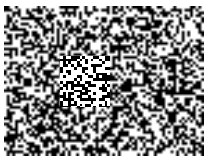
TABLE 8 Examples of biological rhythms and clocks

Living being	Oscillating system	Period
Sand hopper (*Talitrus saltator*)	knows in which direction to flee from the position of the Sun or Moon	circadian
Human (*Homo sapiens*)	gamma waves in the brain	0.023 to 0.03 s
	alpha waves in the brain	0.08 to 0.13 s
	heart beat	0.3 to 1.5 s
	delta waves in the brain	0.3 to 10 s
	blood circulation	30 s
	cellular circahoral rhythms	1 to 2 ks
	rapid-eye-movement sleep period	5.4 ks
	nasal cycle	4 to 14 ks
	growth hormone cycle	11 ks
	suprachiasmatic nuclei (SCN), circadian hormone concentration, temperature, etc.; leads to jet lag	90 ks
	monthly period	2.4(4) Ms
	built-in aging	3.2(3) Gs
Common fly (*Musca domestica*)	wing beat	30 ms
Fruit fly (*Drosophila melanogaster*)	wing beat for courting	34 ms
Most insects (e.g. wasps, fruit flies)	winter approach detection (diapause) by length of day measurement; triggers metabolism changes	yearly
Algae (*Acetabularia*)	Adenosinetriphosphate (ATP) concentration	
Moulds (e.g. *Neurospora crassa*)	conidia formation	circadian
Many flowering plants	flower opening and closing	circadian
Tobacco plant	flower opening clock; triggered by length of days, discovered in 1920 by Garner and Allard	annual
Arabidopsis	circumnutation	circadian
	growth	a few hours
Telegraph plant (*Desmodium gyrans*)	side leaf rotation	200 s
Forsythia europaea, *F. suspensa*, *F. viridissima*, *F. spectabilis*	Flower petal oscillation, discovered by Van Gooch in 2002	5.1 ks

races still do so to this day. That is why runners move anticlockwise. For the same reason, helical stairs in castles are built in such a way that defending right-handers, usually from above, have that hand on the outside.

On the other hand, the clock imitates the shadow of sundials; obviously, this is true on the northern hemisphere only, and only for sundials on the ground, which were the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



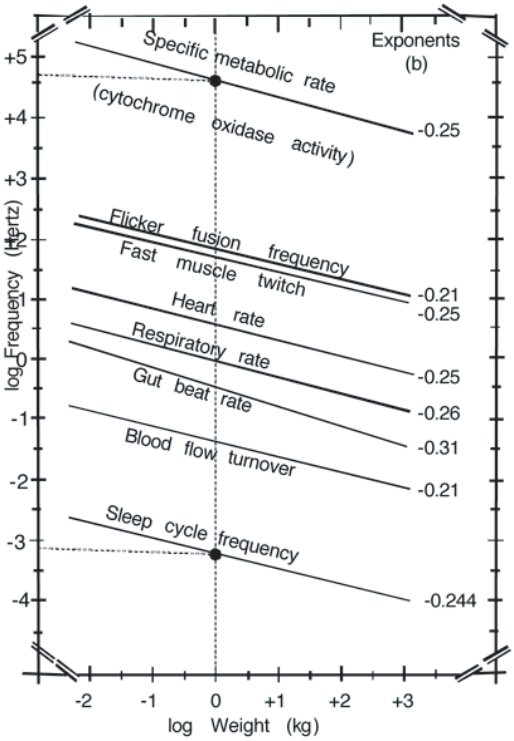


FIGURE 20 How biological rhythms scale with size in mammals (© Enrique Morgado)

most common ones. (The old trick to determine south by pointing the hour hand of a horizontal watch to the Sun and halving the angle between it and the direction of 12 o'clock does not work on the southern hemisphere.) So every clock implicitly continues to state on which hemisphere it was invented. In addition, it also tells us that sundials on walls came in use much later than those on the floor.

Does time flow?

> Wir können keinen Vorgang mit dem 'Ablauf der Zeit' vergleichen – diesen gibt es nicht –, sondern nur mit einem anderen Vorgang (etwa dem Gang des Chronometers).*
>
> Ludwig Wittgenstein, *Tractatus*, 6.3611

The expression 'the flow of time' is often used to convey that in nature change follows after change, in a steady and continuous manner. But though the hands of a clock 'flow', time itself does not. Time is a concept introduced specially to describe the flow of events around us; it does not itself flow, it *describes* flow. Time does not advance. Time is neither linear nor cyclic. The idea that time flows is as hindering to understanding nature as is

* 'We cannot compare any process with 'the passage of time' – there is no such thing – but only with another process (say, with the working of a chronometer).'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Page 717 the idea that mirrors exchange right and left.

The misleading use of the expression 'flow of time', propagated first by some flawed Ref. 35 Greek thinkers and then again by Newton, continues. Aristotle (384/3–322 BCE), careful to think logically, pointed out its misconception, and many did so after him. Nevertheless, expressions such as 'time reversal', the 'irreversibility of time', and the much-abused Challenge 42 e 'time's arrow' are still common. Just read a popular science magazine chosen at random. The fact is: time cannot be reversed, only motion can, or more precisely, only velocities of objects; time has no arrow, only motion has; it is not the flow of time that humans are unable to stop, but the motion of all the objects in nature. Incredibly, there are even books Ref. 36 written by respected physicists that study different types of 'time's arrows' and compare them with each other. Predictably, no tangible or new result is extracted. Time does not flow.

In the same manner, colloquial expressions such as 'the start (or end) of time' should be avoided. A motion expert translates them straight away into 'the start (or end) of motion'.

What is space?

> The introduction of numbers as coordinates [...] is an act of violence [...].
>
> Hermann Weyl, *Philosophie der Mathematik und Naturwissenschaft*.*

Whenever we distinguish two objects from each other, such as two stars, we first of all distinguish their positions. We distinguish positions with our senses of sight, touch, hearing and proprioperception. Position is therefore an important aspect of the physical state of an object. A position is taken by only one object at a time. Positions are limited. The set of all available positions, called *(physical) space*, acts as both a container and a background.

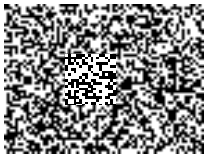
Closely related to space and position is *size*, the set of positions an objects occupies. Small objects occupy only subsets of the positions occupied by large ones. We will discuss size shortly.

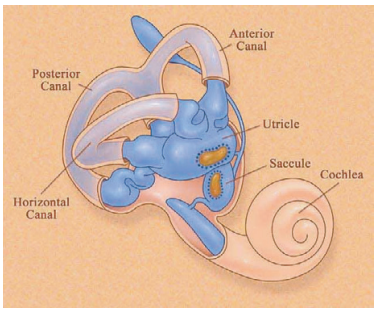
How do we deduce space from observations? During childhood, humans (and most higher animals) learn to bring together the various perceptions of space, namely the visual, the tactile, the auditory, the kinaesthetic, the vestibular etc., into one coherent set of experiences and description. The result of this learning process is a certain concept of space in the brain. Indeed, the question 'where?' can be asked and answered in all languages of the world. Being more precise, adults derive space from distance measurements. The concepts of length, area, volume, angle and solid angle are all deduced with their help. Geometers, surveyors, architects, astronomers, carpet salesmen and producers of metre sticks base their trade on distance measurements. Space is a concept formed to summarize all the distance relations between objects for a precise description of observations.

Metre sticks work well only if they are straight. But when humans lived in the jungle, there were no straight objects around them. No straight rulers, no straight tools, noth-

* Hermann Weyl (1885–1955) was one of the most important mathematicians of his time, as well as an important theoretical physicist. He was one of the last universalists in both fields, a contributor to quantum theory and relativity, father of the term 'gauge' theory, and author of many popular texts.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009





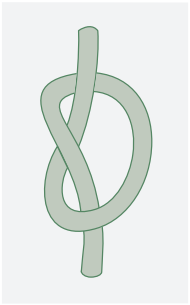


FIGURE 21 Two proofs of the three-dimensionality of space: the vestibular labyrinth in the inner ear of mammals (here a human) and a knot (© Northwestern University)

Challenge 43 s ing. Today, a cityscape is essentially a collection of straight lines. Can you describe how humans achieved this?

Once humans came out of the jungle with their newly built metre sticks, they collected a wealth of results. The main ones are listed in Table 9; they are easily confirmed by personal experience. Objects can take positions in an apparently *continuous* manner: there indeed are more positions than can be counted.* Size is captured by defining the distance between various positions, called *length*, or by using the field of view an object takes when touched, called its *surface*. Length and surface can be measured with the help of a metre stick. Selected measurement results are given in Table 10. The length of objects is independent of the person measuring it, of the position of the objects and of their orientation. In daily life the sum of angles in any triangle is equal to two right angles. There are no limits in space.

Experience shows us that space has three dimensions; we can define sequences of positions in precisely three independent ways. Indeed, the inner ear of (practically) all vertebrates has three semicircular canals that sense the body's acceleration in the three dimensions of space, as shown in Figure 21.** Similarly, each human eye is moved by
Challenge 44 s three pairs of muscles. (Why three?) Another proof that space has three dimensions is provided by shoelaces: if space had more than three dimensions, shoelaces would not be useful, because knots exist only in three-dimensional space. But why does space have three dimensions? This is one of the most difficult question of physics; it will be answered only in the very last part of our walk.

Challenge 45 s It is often said that thinking in four dimensions is impossible. That is wrong. Just try. For example, can you confirm that in four dimensions knots are impossible?

Like time intervals, length intervals can be described most precisely with the help of *real numbers*. In order to simplify communication, standard *units* are used, so that everybody uses the same numbers for the same length. Units allow us to explore the general properties of *Galilean space* experimentally: space, the container of objects, is continuous, three-dimensional, isotropic, homogeneous, infinite, Euclidean and unique or 'absolute'. In mathematics, a structure or mathematical concept with all the properties just mentioned is called a three-dimensional *Euclidean space*. Its elements, *(mathematical) points*,

* For a definition of uncountability, see page 825.

** Note that saying that space has three dimensions *implies* that space is continuous; the Dutch mathematician and philosopher Luitzen Brouwer (b. 1881 Overschie, d. 1966 Blaricum) showed that dimensionality is only a useful concept for continuous sets.

are described by three real parameters. They are usually written as

$$(x, y, z) \tag{1}$$

and are called *coordinates*. They specify and order the location of a point in space. (For the precise definition of Euclidean spaces, see page 77.)

What is described here in just half a page actually took 2000 years to be worked out, mainly because the concepts of 'real number' and 'coordinate' had to be discovered first. The first person to describe points of space in this way was the famous mathematician and philosopher René Descartes*, after whom the coordinates of expression (1) are named *Cartesian*.

Like time, space is a *necessary* concept to describe the world. Indeed, space is automatically introduced when we describe situations with many objects. For example, when

* René Descartes or Cartesius (b. 1596 La Haye, d. 1650 Stockholm), French mathematician and philosopher, author of the famous statement 'je pense, donc je suis', which he translated into 'cogito ergo sum' – I think therefore I am. In his view this is the only statement one can be sure of.

TABLE 10 Some measured distance values

Observation	Distance
Galaxy Compton wavelength	10^{-85} m (calculated only)
Planck length, the shortest measurable length	10^{-32} m
Proton diameter	1 fm
Electron Compton wavelength	2.426 310 215(18) pm
Hydrogen atom size	30 pm
Smallest eardrum oscillation detectable by human ear	50 pm
Size of small bacterium	0.2 µm
Wavelength of visible light	0.4 to 0.8 µm
Point: diameter of smallest object visible with naked eye	20 µm
Diameter of human hair (thin to thick)	30 to 80 µm
Total length of DNA in each human cell	2 m
Largest living thing, the fungus *Armillaria ostoyae*	3 km
Highest human-built structure, the Warsaw radio mast	647 m
Largest spider webs in Mexico	*c.* 5 km
Length of Earth's Equator	40 075 014.8(6) m
Total length of human nerve cells	$8 \cdot 10^5$ km
Average distance to Sun	149 597 870 691(30) m
Light year	9.5 Pm
Distance to typical star at night	10 Em
Size of galaxy	1 Zm
Distance to Andromeda galaxy	28 Zm
Most distant visible object	125 Ym

many spheres lie on a billiard table, we cannot avoid using space to describe the relations between them. There is no way to avoid using spatial concepts when talking about nature.

Even though we need space to talk about nature, it is still interesting to ask why this is possible. For example, since length measurement methods do exist, there must be a *natural* or *ideal* way to measure distances, sizes and straightness. Can you find it? Challenge 46 s

As in the case of time, each of the properties of space just listed has to be checked. And again, careful observations will show that each property is an approximation. In simpler and more drastic words, *all* of them are wrong. This confirms Weyl's statement at the beginning of this section. In fact, his statement about the violence connected with the introduction of numbers is told by every forest in the world, and of course also by the one at the foot of Motion Mountain. The rest of our adventure will show this.

Are space and time absolute or relative?

In everyday life, the concepts of Galilean space and time include two opposing aspects; the contrast has coloured every discussion for several centuries. On the one hand, space and time express something invariant and permanent; they both act like big containers for all the objects and events found in nature. Seen this way, space and time have an existence of their own. In this sense one can say that they are fundamental or *absolute*. On the other hand, space and time are tools of description that allow us to talk about rela-

TABLE 11 Length measurement devices in biological and engineered systems

Measurement	Device	Range
Humans		
Measurement of body shape, e.g. finger distance, eye position, teeth distance	muscle sensors	0.3 mm to 2 m
Measurement of object distance	stereoscopic vision	1 to 100 m
Measurement of object distance	sound echo effect	0.1 to 1000 m
Animals		
Measurement of walking distance by desert ants	step counter	up to 100 m
Measurement of flight distance by honey bees	eye	up to 3 km
Measurement of swimming distance by sharks	magnetic field map	up to 1000 km
Measurement of prey distance by snakes	infrared sensor	up to 2 m
Measurement of prey distance by bats, dolphins, and hump whales	sonar	up to 100 m
Measurement of prey distance by raptors	vision	0.1 to 1000 m
Machines		
Measurement of object distance by laser	light reflection	0.1 m to 400 Mm
Measurement of object distance by radar	radio echo	0.1 to 50 km
Measurement of object length	interferometer	0.5 µm to 50 km
Measurement of star, galaxy or quasar distance	intensity decay	up to 125 Ym
Measurement of particle size	accelerator	down to 10^{-18} m

tions between objects. In this view, they do not have any meaning when separated from objects, and only result from the relations between objects; they are derived, relational or *relative*. Which of these viewpoints do you prefer? The results of physics have alternately favoured one viewpoint or the other. We will repeat this alternation throughout our adventure, until we find the solution. And obviously, it will turn out to be a third option.

Challenge 47 e

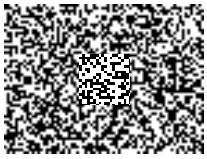
Ref. 37

Size – why area exists, but volume does not

A central aspect of objects is their size. As a small child, under school age, every human learns how to use the properties of size and space in their actions. As adults seeking precision, the definition of *distance* as the difference between coordinates allows us to define *length* in a reliable way. It took hundreds of years to discover that this is *not* the case. Several investigations in physics and mathematics led to complications.

The physical issues started with an astonishingly simple question asked by Lewis

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



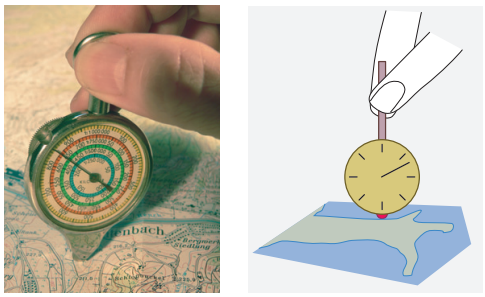


FIGURE 24 A curvimeter or odometer (photograph © Frank Müller)

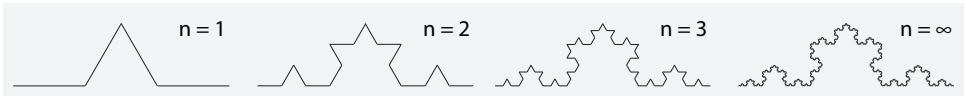

FIGURE 25 A fractal: a self-similar curve of *infinite* length (far right), and its construction

Richardson:* How long is the western coastline of Britain?

Following the coastline on a map using an odometer, a device shown in Figure 24, Richardson found that the length l of the coastline depends on the scale s (say 1 : 10 000 or 1 : 500 000) of the map used:

$$l = l_0 \, s^{0.25} \tag{2}$$

(Richardson found other numbers for other coasts.) The number l_0 is the length at scale 1 : 1. The main result is that the larger the map, the longer the coastline. What would happen if the scale of the map were increased even beyond the size of the original? The length would increase beyond all bounds. Can a coastline really have *infinite* length? Yes, it can. In fact, mathematicians have described many such curves; they are called *fractals*. An infinite number of them exist, and Figure 25 shows one example.** Can you construct another? Challenge 48 e

Length has other strange properties. The Italian mathematician Giuseppe Vitali was the first to discover that it is possible to cut a line segment of length 1 into pieces that can be reassembled – merely by shifting them in the direction of the segment – into a line segment of length 2. Are you able to find such a division using the hint that it is only possible using infinitely many pieces? Challenge 49 d

To sum up, length is well defined for lines that are straight or nicely curved, but not for intricate lines, or for lines made of infinitely many pieces. We therefore avoid fractals and other strangely shaped curves in the following, and we take special care when we talk about infinitely small segments. These are the central assumptions in the first two parts of this adventure, and we should never forget them. We will come back to these

* Lewis Fray Richardson (1881–1953), English physicist and psychologist.

** Most of these curves are *self-similar*, i.e., they follow scaling 'laws' similar to the above-mentioned. The term 'fractal' is due to the Polish mathematician Benoît Mandelbrot and refers to a strange property: in a certain sense, they have a non-integral number D of dimensions, despite being one-dimensional by construction. Mandelbrot saw that the non-integer dimension was related to the exponent e of Richardson by $D = 1 + e$, thus giving $D = 1.25$ in the example above. Ref. 38

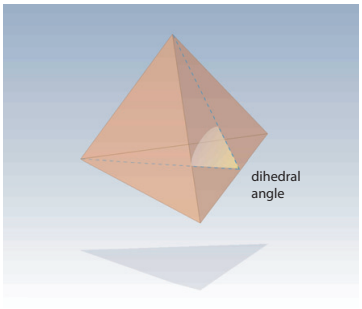

FIGURE 26 A polyhedron with one of its dihedral angles (© Luca Gastaldi)

assumptions in the last part of our adventure.

In fact, all these problems pale when compared with the following problem. Commonly, area and volume are defined using length. You think that it is easy? You're wrong, as well as being a victim of prejudices spread by schools around the world. To define area and volume with precision, their definitions must have two properties: the values must be *additive*, i.e., for finite and infinite sets of objects, the total area and volume have to be the sum of the areas and volumes of each element of the set; and they must be *rigid*, i.e., if one cuts an area or a volume into pieces and then rearranges the pieces, the value remains the same. Are such definitions possible? In other words, do such concepts of volume and area exist?

For areas in a plane, one proceeds in the following standard way: one defines the area A of a rectangle of sides a and b as $A = ab$; since any polygon can be rearranged into a rectangle with a finite number of straight cuts, one can then define an area value for all polygons. Subsequently, one can define area for nicely curved shapes as the limit of the sum of infinitely many polygons. This method is called *integration*; it is introduced in detail in the section on physical action.

Challenge 50 s

Page 195

However, integration does not allow us to define area for arbitrarily bounded regions. (Can you imagine such a region?) For a complete definition, more sophisticated tools are needed. They were discovered in 1923 by the famous mathematician Stefan Banach.* He proved that one can indeed define an area for any set of points whatsoever, even if the border is not nicely curved but extremely complicated, such as the fractal curve previously mentioned. Today this generalized concept of area, technically a 'finitely additive isometrically invariant measure,' is called a *Banach measure* in his honour. Mathematicians sum up this discussion by saying that since in two dimensions there is a Banach measure, there is a way to define the concept of area – an additive and rigid measure – for any set of points whatsoever.**

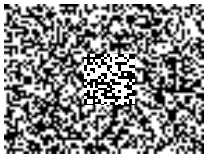
Challenge 51 s

What is the situation in *three* dimensions, i.e., for volume? We can start in the same way as for area, by defining the volume V of a rectangular polyhedron with sides a, b,

* Stefan Banach (Krakow, 1892–Lvov, 1945), important Polish mathematician.

** Actually, this is true only for sets on the plane. For curved surfaces, such as the surface of a sphere, there are complications that will not be discussed here. In addition, the problems mentioned in the definition of length of fractals also reappear for area if the surface to be measured is not flat. A typical example is the area of the human lung: depending on the level of details examined, one finds area values from a few up to over a hundred square metres.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



c as $V = abc$. But then we encounter a first problem: a general polyhedron cannot be cut into a cube by straight cuts! The limitation was discovered in 1900 and 1902 by Max Dehn.* He found that the possibility depends on the values of the edge angles, or dihedral angles, as the mathematicians call them. If one ascribes to every edge of a general polyhedron a number given by its length l times a special function $g(\alpha)$ of its dihedral angle α, then Dehn found that the sum of all the numbers for all the edges of a solid does not change under dissection, provided that the function fulfils $g(\alpha + \beta) = g(\alpha) + g(\beta)$ and $g(\pi) = 0$. An example of such a strange function g is the one assigning the value 0 to any rational multiple of π and the value 1 to a basis set of irrational multiples of π. The values for all other dihedral angles of the polyhedron can then be constructed by combination of rational multiples of these basis angles. Using this function, you may then Challenge 52 s deduce for yourself that a cube cannot be dissected into a regular tetrahedron because their respective Dehn invariants are different.**

Despite the problems with Dehn invariants, one *can* define a rigid and additive concept of volume for polyhedra, since for all polyhedra and, in general, for all 'nicely curved' shapes, one can again use integration for the definition of their volume.

Now let us consider general shapes and general cuts in three dimensions, not just the 'nice' ones mentioned so far. We then stumble on the famous *Banach–Tarski theorem* (or Ref. 39 paradox). In 1924, Stefan Banach and Alfred Tarski*** proved that it is possible to cut one sphere into five pieces that can be recombined to give two spheres, each the size of the original. This counter-intuitive result is the Banach–Tarski theorem. Even worse, another version of the theorem states: take any two sets not extending to infinity and containing a solid sphere each; then it is always possible to dissect one into the other with a *finite* number of cuts. In particular it is possible to dissect a pea into the Earth, or vice versa. Size does not count!**** Volume is thus not a useful concept at all.

The Banach–Tarski theorem raises two questions: first, can the result be applied to gold or bread? That would solve many problems. Second, can it be applied to empty Challenge 53 s space? In other words, are matter and empty space continuous? Both topics will be explored later in our walk; each issue will have its own, special consequences. For the moment, we eliminate this troubling issue by restricting our interest to smoothly curved shapes (and cutting knives). With this restriction, volumes of matter and of empty space do behave nicely: they are additive and rigid, and show no paradoxes.***** Indeed, the cuts required for the Banach–Tarski paradox are not smooth; it is not possible to perform them with an everyday knife, as they require (infinitely many) infinitely sharp bends performed with an infinitely sharp knife. Such a knife does not exist. Nevertheless, we keep

* Max Dehn (1878–1952), German mathematician, student of David Hilbert.

** This is also told in the beautiful book by M. Aigler & G. M. Ziegler, *Proofs from the Book*, Springer Verlag, 1999. The title is due to the famous habit of the great mathematician Paul Erdős to imagine that all beautiful mathematical proofs can be assembled in the 'book of proofs'.

*** Alfred Tarski (b. 1902 Warsaw, d. 1983 Berkeley), Polish mathematician.

**** The proof of the result does not need much mathematics; it is explained beautifully by Ian Stewart in Paradox of the spheres, *New Scientist*, 14 January 1995, pp. 28–31. The proof is based on the axiom of choice, Page 823 which is presented later on. The Banach–Tarski paradox also exists in four dimensions, as it does in any Ref. 40 higher dimension. More mathematical detail can be found in the beautiful book by Stan Wagon.

***** Mathematicians say that a so-called *Lebesgue measure* is sufficient in physics. This countably additive isometrically invariant measure provides the most general way to define a volume.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

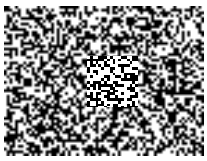


FIGURE 27 Straight lines found in nature: cerussite (picture width approx. 3 mm, © Stephan Wolfsried) and selenite (picture width approx. 15 m, © Arch. Speleoresearch & Films/La Venta at www.laventa.it and www.naica.com.mx)

in the back of our mind that the size of an object or of a piece of empty space is a tricky quantity – and that we need to be careful whenever we talk about it.

What is straight?

When you see a solid object with a straight edge, it is a 99 %-safe bet that it is man-made. Of course, there are exceptions, as shown in Figure 27.* The largest crystals ever found are
Ref. 42 18 m in length. But in general, the contrast between the objects seen in a city – buildings, furniture, cars, electricity poles, boxes, books – and the objects seen in a forest – trees, plants, stones, clouds – is evident: in the forest nothing is straight or flat, in the city most objects are. How is it possible for humans to produce straight objects while there are almost none to be found in nature?

Page 358 Any forest teaches us the origin of straightness; it presents tall tree trunks and rays of daylight entering from above through the leaves. For this reason we call a line *straight* if it touches either a plumb-line or a light ray along its whole length. In fact, the two
Challenge 54 s definitions are equivalent. Can you confirm this? Can you find another definition? Obviously, we call a surface *flat* if for any chosen orientation and position the surface touches a plumb-line or a light ray along its whole extension.

In summary, the concept of straightness – and thus also of flatness – is defined with the help of bodies or radiation. In fact, all spatial concepts, like all temporal concepts, require motion for their definition.

A hollow Earth?

Space and straightness pose subtle challenges. Some strange people maintain that all humans live on the *inside* of a sphere; they (usually) call this the *hollow Earth theory*. They claim that the Moon, the Sun and the stars are all near the centre of the hollow sphere. They also explain that light follows curved paths in the sky and that when conventional physicists talk about a distance r from the centre of the Earth, the real hollow Earth dis-
Challenge 55 s tance is $r_{\text{he}} = R^2_{\text{Earth}}/r$. Can you show that this model is wrong? Roman Sexl** used to

* Another famous exception, unrelated to atomic structures, is the well-known Irish geological formation
Page 312 called the Giant's Causeway. Other candidates that might come to mind, such as certain bacteria which have
Ref. 41 (almost) square or (almost) triangular shapes are not counter-examples, as the shapes are only approximate.

FIGURE 28 A photograph of the Earth – seen from the direction of the Sun (NASA)

ask this question to his students and fellow physicists. The answer is simple: if you think you have an argument to show that this view is wrong, you are mistaken! There is *no way* of showing that such a view is wrong. It is possible to explain the horizon, the appearance of day and night, as well as the satellite photographs of the round Earth, such as Figure 28. To explain what happened during a flight to the Moon is also fun. A coherent hollow Earth view is fully *equivalent* to the usual picture of an infinitely extended space. We will come back to this problem in the section on general relativity.

0.000 056	$5.6 \cdot 10^{-5}$	56 000	$5.6 \cdot 10^4$
0.000 01	10^{-5} etc.	100 000	10^5 etc.

* *

Scientists use a special way to write large and small numbers, explained in Table 12.

* *

Ref. 43 In 1996 the smallest experimentally probed distance was 10^{-19} m, achieved between quarks at Fermilab. (To savour the distance value, write it down without the exponent.)
Challenge 83 s What does this measurement mean for the continuity of space?

* *

Zeno, the Greek philosopher, discussed in detail what happens to a moving object at a given instant of time. To discuss with him, you decide to build the fastest possible shutter for a photographic camera that you can imagine. You have all the money you want. What
Challenge 84 s is the shortest shutter time you would achieve?

* *

Can you prove Pythagoras' theorem by geometrical means alone, without using
Challenge 85 s coordinates? (There are more than 30 possibilities.)

* *

Page 62 Why are most planets and moons, including ours, (almost) spherical (see, for example,
Challenge 86 s Figure 28)?

* *

A rubber band connects the tips of the two hands of a clock. What is the path followed
Challenge 87 s by the mid-point of the band?

* *

There are two important quantities connected to angles. As shown in Figure 34, what is usually called a *(plane) angle* is defined as the ratio between the lengths of the arc and the radius. A right angle is $\pi/2$ *radian* (or $\pi/2$ rad) or 90°.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

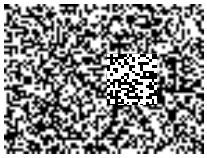

FIGURE 34 The definition of plane and solid angles

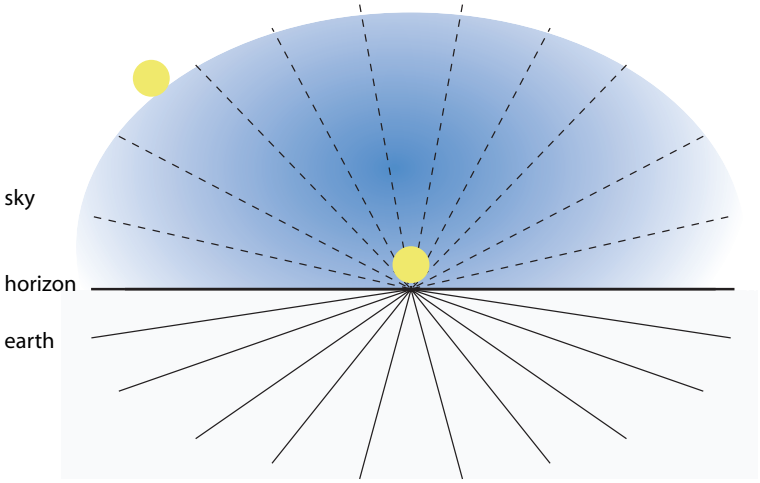

FIGURE 35 How the apparent size of the Moon and the Sun changes during a day

The *solid angle* is the ratio between area and the square of the radius. An eighth of a sphere is $\pi/2$ *steradian* or $\pi/2$ sr. (Mathematicians, of course, would simply leave out the steradian unit.) As a result, a small solid angle shaped like a cone and the angle of the cone tip are *different*. Can you find the relationship? Challenge 88 s

* *

The definition of angle helps to determine the size of a firework display. Measure the time T, in seconds, between the moment that you see the rocket explode in the sky and the moment you hear the explosion, measure the (plane) angle α – pronounced 'alpha' – of the ball formed by the firework with your hand. The diameter D is

$$D \approx \frac{6\,\mathrm{m}}{s\,^\circ} T \alpha \,. \tag{3}$$

Why? For more about fireworks, see the cc.oulu.fi/~kempmp website. By the way, the angular distance between the knuckles of an extended fist are about 3°, 2° and 3°, the size of an extended hand 20°. Can you determine the other angles related to your hand? Challenge 89 e Challenge 90 s

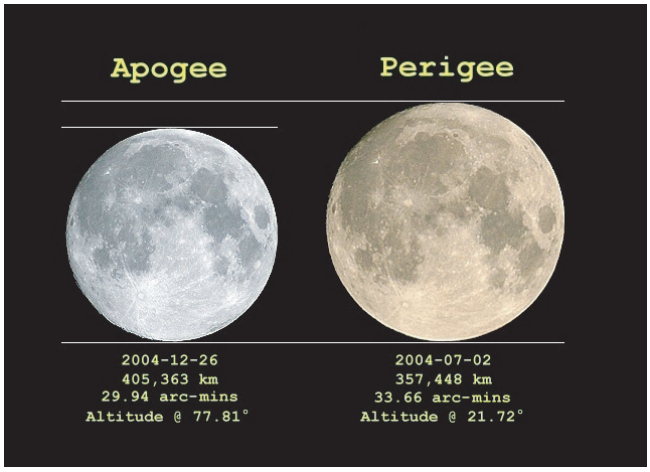

FIGURE 36 How the size of the Moon actually changes during its orbit (© Anthony Ayiomamitis)

* *

Using angles, the *sine*, *cosine*, *tangent*, *cotangent*, *secant* and *cosecant* can be defined. Look them up in your trigonometry text from high school. Can you confirm that $\sin 15° = (\sqrt{6} - \sqrt{2})/4$, $\sin 18° = (-1 + \sqrt{5})/4$, $\sin 36° = \sqrt{10 - 2\sqrt{5}}/4$, $\sin 54° = (1 + \sqrt{5})/4$ and that $\sin 72° = \sqrt{10 + 2\sqrt{5}}/4$? Can you show also that

Challenge 91 e

$$\frac{\sin x}{x} = \cos\frac{x}{2}\cos\frac{x}{4}\cos\frac{x}{8}\ldots \tag{4}$$

is correct?

* *

Measuring angular size with the eye only is tricky. For example, can you say whether the Moon is larger or smaller than the nail of your thumb at the end of your extended arm? Angular size is not an intuitive quantity; it requires measurement instruments.

Challenge 92 e

A famous example, shown in Figure 35, illustrates the difficulty of estimating angles. Both the Sun and the Moon seem larger when they are on the horizon. In ancient times, Ptolemy explained this so-called *Moon illusion* by an unconscious apparent distance change induced by the human brain. Indeed, the Moon illusion disappears when you look at the Moon through your legs. In fact, the Moon is even *further away* from the observer when it is just above the horizon, and thus its image is *smaller* than it was a few hours earlier, when it was high in the sky. Can you confirm this?

Challenge 93 s

The Moon's angualr size changes even more due to another effect: the orbit of the Moon round the Earth is elliptical. An example of the consequence is shown in Figure 36.

* *

Galileo also made mistakes. In his famous book, the *Dialogues*, he says that the curve formed by a thin chain hanging between two nails is a parabola, i.e., the curve defined by $y = x^2$. That is not correct. What is the correct curve? You can observe the shape

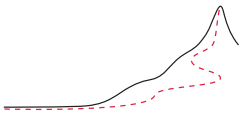
Summary about everyday space and time

Motion defines speed, time and length. Observations of everyday life and precision experiments are conveniently and precisely described by modelling velocity as a Euclidean vector, space as a three-dimensional Euclidean space, and time as a one-dimensional real line. Modelling velocity, time and space as continuous quantities is precise and convenient. However, this common model cannot be checked. For example, no experiments can check distances larger than 10^{25} m or smaller than 10^{-25} m; the model is likely to be incorrect there. We will find out later on that this is indeed the case.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 3

HOW TO DESCRIBE MOTION – KINEMATICS

> La filosofia è scritta in questo grandissimo libro che continuamente ci sta aperto innanzi agli occhi (io dico l'universo) ... Egli è scritto in lingua matematica.*
>
> Galileo Galilei, *Il saggiatore* VI.

Experiments show that the properties of Galilean time and space are extracted from the environment by most higher animals and by young children. Among others, this has been tested for cats, dogs, rats, mice, ants, fish and many other species. They all find the same results.

First of all, *motion is change of position with time*. This description is illustrated by rapidly flipping the lower left corners of this book, starting at page 190. Each page simulates an instant of time, and the only change that takes place during motion is in the position of the object, represented by the dark spot. The other variations from one picture to the next, which are due to the imperfections of printing techniques, can be taken to simulate the inevitable measurement errors.

Calling 'motion' the change of position with time is *neither* an explanation *nor* a definition, since both the concepts of time and position are deduced from motion itself. It is only a *description* of motion. Still, the description is useful, because it allows for high precision, as we will find out by exploring gravitation and electrodynamics. After all, precision is our guiding principle during this promenade. Therefore the detailed description of changes in position has a special name: it is called *kinematics*.

The idea of change of positions implies that the object can be *followed* during its motion. This is not obvious; in the section on quantum theory we fill find examples where this is impossible. But in everyday life, objects can always be tracked. The set of all positions taken by an object over time forms ist *path* or *trajectory*. The origin of this concept is evident when one watches fireworks or again the flip film in the lower left corners starting at page 190.

Ref. 46

In everyday life, animals and humans agree on the Euclidean properties of velocity, space and time. In particular, this implies that a trajectory can be described by specifying three numbers, three *coordinates* (x, y, z) – one for each dimension – as continuous functions of time t. (Functions are defined in detail on page 826.) This is usually written as $\boldsymbol{x} = \boldsymbol{x}(t) = (x(t), y(t), z(t))$. For example, already Galileo found, using stopwatch

* Science is written in this huge book that is continuously open before our eyes (I mean the universe) ... It is written in mathematical language.

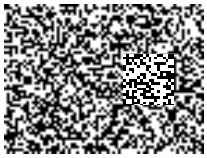

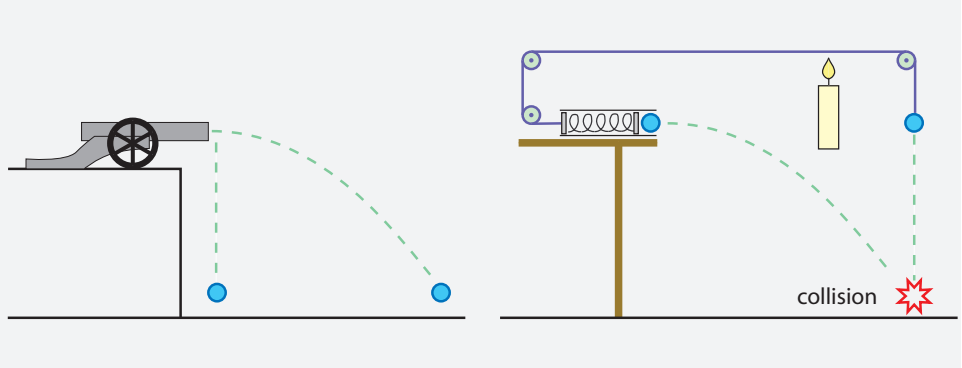

FIGURE 41 Two ways to test that the time of free fall does not depend on horizontal velocity

and ruler, that the height z of any thrown or falling stone changes as

$$z(t) = z_0 + v_0\,(t - t_0) - \tfrac{1}{2} g\,(t - t_0)^2 \tag{5}$$

where t_0 is the time the fall starts, z_0 is the initial height, v_0 is the initial velocity in the vertical direction and $g = 9.8\,\mathrm{m/s^2}$ is a constant that is found to be the same, within about one part in 300, for all falling bodies on all points of the surface of the Earth. Where do the value $9.8\,\mathrm{m/s^2}$ and its slight variations come from? A preliminary answer will be given shortly, but the complete elucidation will occupy us during the larger part of this hike.

Ref. 47

Equation (5) allows us to determine the depth of a well, given the time a stone takes to reach its bottom. The equation also gives the speed v with which one hits the ground after jumping from a tree, namely $v = \sqrt{2gh}$. A height of 3 m yields a velocity of 27 km/h. The velocity is thus proportional only to the square root of the height. Does this mean that one's strong fear of falling results from an overestimation of its actual effects?

Challenge 108 s

Challenge 109 s

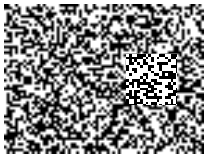
Galileo was the first to state an important result about free fall: the motions in the horizontal and vertical directions are *independent*. He showed that the time it takes for a cannon ball that is shot exactly horizontally to fall is *independent* of the strength of the gunpowder, as shown in Figure 41. Many great thinkers did not agree with this statement even after his death: in 1658 the Academia del Cimento even organized an experiment to check this assertion, by comparing the flying cannon ball with one that simply fell vertically. Can you imagine how they checked the simultaneity? Figure 41 also shows how you can check this at home. In this experiment, whatever the spring load of the cannon, the two bodies will always collide in mid-air (if the table is high enough), thus proving the assertion.

Ref. 48

Challenge 110 s

In other words, a flying canon ball is not accelerated in the horizontal direction. Its horizontal motion is simply unchanging. By extending the description of equation (5)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



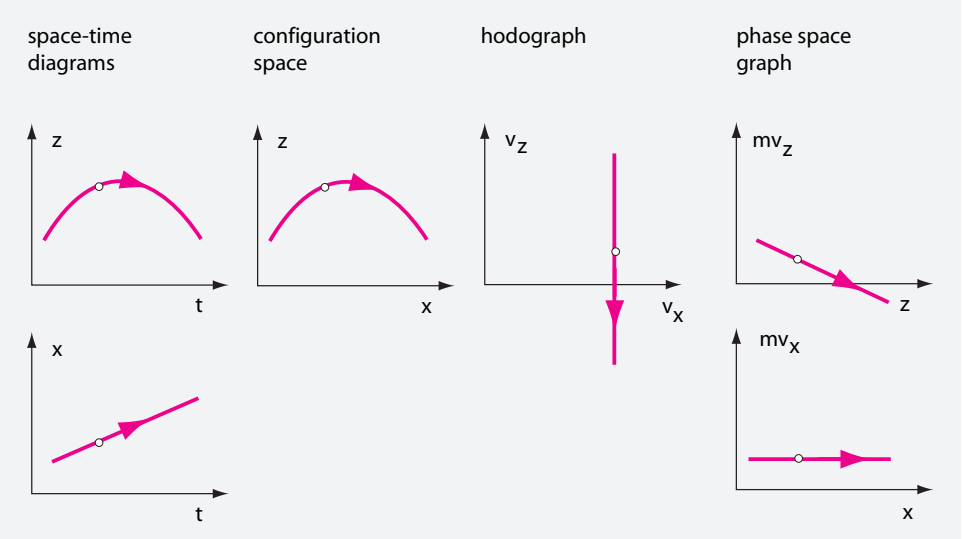


FIGURE 42 Various types of graphs describing the same path of a thrown stone

with the two expressions for the horizontal coordinates x and y, namely

$$x(t) = x_0 + v_{x0}(t - t_0)$$
$$y(t) = y_0 + v_{y0}(t - t_0)\,, \tag{6}$$

a *complete* description for the path followed by thrown stones results. A path of this shape is called a *parabola*; it is shown in Figures 18, 41 and 42. (A parabolic shape is also used for light reflectors inside pocket lamps or car headlights. Can you show why?)

Page 45
Challenge 111 s
Ref. 49

Physicists enjoy generalizing the idea of a path. As Figure 42 shows, a path is a trace left in a diagram by a moving object. Depending on what diagram is used, these paths have different names. Hodographs are used in weather forecasting. Space-time diagrams are useful to make the theory of relativity accessible. The *configuration space* is spanned by the coordinates of all particles of a system. For many particles, it is has a high number of dimensions. It plays an important role in self-organization. The difference between chaos and order can be described as a difference in the properties of paths in configuration space. The phase space diagram is also called *state space diagram*. It plays an essential role in thermodynamics.

Throwing, jumping and shooting

The kinematic description of motion is useful for answering a whole range of questions.

* *

What is the upper limit for the long jump? The running speed world record in 1997 was 12 m/s ≈ 43 km/h by Ben Johnson, and the women's record was 11 m/s ≈ 40 km/h. However, long jumpers never run much faster than about 9.5 m/s. How much extra jump

Ref. 50

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

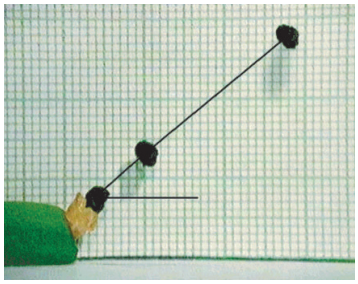

FIGURE 43 Three superimposed images of a frass pellet shot away by a caterpillar inside a rolled-up leaf (© Stanley Caveney)

distance could they achieve if they could run full speed? How could they achieve that? In addition, long jumpers take off at angles of about 20°, as they are not able to achieve a higher angle at the speed they are running. How much would they gain if they could achieve 45°? (Is 45° the optimal angle?)

Ref. 51

Challenge 112 s

* *

How can the speed of falling rain be measured using an umbrella? The answer is important: the same method can also be used to measure the speed of light, as we will find out later. (Can you guess how?)

Challenge 113 s

Page 403

* *

When a dancer jumps in the air, how many times can it rotate around its vertical axis before arriving back on earth?

Challenge 114 ny

* *

Numerous species of moth and butterfly caterpillars shoot away their frass – to put it more crudely: their shit – so that its smell does not help predators to locate them. Stanley Caveney and his team took photographs of this process. Figure 43 shows a caterpillar (yellow) of the skipper *Calpodes ethlius* inside a rolled up green leaf caught in the act. Given that the record distance observed is 1.5 m (though by another species, *Epargyreus clarus*), what is the ejection speed? How do caterpillars achieve it?

Ref. 52

Challenge 115 s

* *

What is the horizontal distance one can reach by throwing a stone, given the speed and the angle from the horizontal at which it is thrown?

Challenge 116 s

* *

What is the maximum numbers of balls that could be juggled at the same time?

Challenge 117 s

* *

Is it true that rain drops would kill if it weren't for the air resistance of the atmosphere? What about hail?

Challenge 118 s

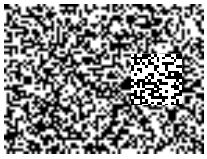

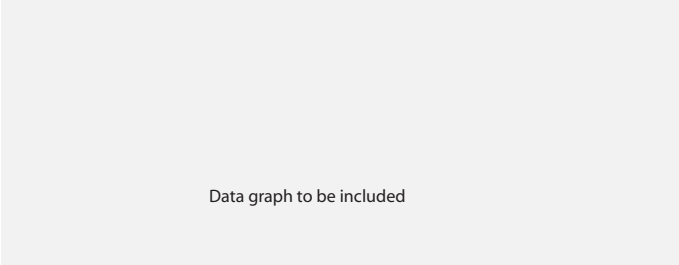

FIGURE 44 The height achieved by jumping animals

Challenge 119 s Are bullets, fired into the air from a gun, dangerous when they fall back down?

* *

Challenge 120 s Police finds a dead human body at the bottom of cliff with a height of 30 m, at a distance of 12 m from the cliff. Was it suicide or murder?

* *

Challenge 121 s Most animals, regardless of their size, achieve jumping heights of at most 2 m, as shown in Figure 44. The explanation of this fact takes only two lines. Can you find it?

The last two issues arise because equation (5) does not hold in all cases. For example, leaves or potato crisps do not follow it. As Galileo already knew, this is a consequence of air resistance; we will discuss it shortly. Because of air resistance, the path of a stone is not always a parabola.

Challenge 122 s In fact, there are other situations where the path of a falling stone is not a parabola. Can you find one?

Enjoying vectors

Physical quantities with a defined direction, such as speed, are described with three numbers, or three components, and are called *vectors*. Learning to calculate with such multi-component quantities is an important ability for many sciences. Here is a summary.

Vectors can be pictured by small arrows. Note that vectors do not have specified points at which they start: two arrows with same direction and the same length are the *same* vector, even if they start at different points in space. Since vectors behave like arrows, they can be added and they can be multiplied by numbers. For example, stretching an arrow $\boldsymbol{a} = (a_x, a_y, a_z)$ by a number c corresponds, in component notation, to the vector $c\boldsymbol{a} = (ca_x, ca_y, ca_z)$.

In precise, mathematical language, a vector is an element of a set, called *vector space*, in which the following properties hold for all vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ and for all numbers c and d:

$$c(\boldsymbol{a} + \boldsymbol{b}) = c\boldsymbol{a} + c\boldsymbol{b} \quad , \quad (c + d)\boldsymbol{a} = c\boldsymbol{a} + d\boldsymbol{a} \quad , \quad (cd)\boldsymbol{a} = c(d\boldsymbol{a}) \quad \text{and} \quad 1\boldsymbol{a} = \boldsymbol{a} \; . \tag{7}$$

Examples of vector spaces are the set of all *positions* of an object, or the set of all its

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

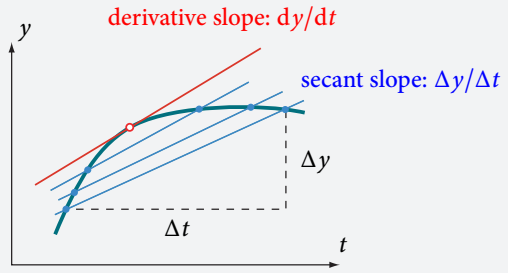

FIGURE 45 The derivative in a point as the limit of secants

Challenge 123 s possible velocities. Does the set of all rotations form a vector space?

All vector spaces allow the definition of a unique *null vector* and of one *negative vector* Challenge 124 e for each vector.

In most vector spaces of importance in science the concept of *length* (specifying the 'magnitude') can be introduced. This is done via an intermediate step, namely the introduction of the scalar product of two vectors. The *scalar product* between two vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ is a number that satisfies

$$\boldsymbol{aa} \geqslant 0\,,\ \boldsymbol{ab} = \boldsymbol{ba}\,,\ (\boldsymbol{a}+\boldsymbol{a}')\boldsymbol{b} = \boldsymbol{ab}+\boldsymbol{a}'\boldsymbol{b}\,,\ \boldsymbol{a}(\boldsymbol{b}+\boldsymbol{b}') = \boldsymbol{ab}+\boldsymbol{ab}' \text{ and } (c\boldsymbol{a})\boldsymbol{b} = \boldsymbol{a}(c\boldsymbol{b}) = c(\boldsymbol{ab})\,. \tag{8}$$

This definition of a scalar product is not unique; however, there is a *standard* scalar product. In Cartesian coordinate notation, the standard scalar product is given by

$$\boldsymbol{ab} = a_x b_x + a_y b_y + a_z b_z\,. \tag{9}$$

If the scalar product of two vectors vanishes the two vectors are *orthogonal*, at a right Challenge 125 e angle to each other. (Show it!)

The *length* or *norm* of a vector can then be defined as the square root of the scalar product of a vector with itself: $a = \sqrt{\boldsymbol{aa}}$. Often, and also in this text, lengths are written in italic letters, whereas vectors are written in bold letters. A vector space with a scalar product is called an *Euclidean* vector space.

The scalar product is also useful for specifying directions. Indeed, the scalar product between two vectors encodes the angle between them. Can you deduce this important Challenge 126 s relation?

What is rest? What is velocity?

In the Galilean description of nature, motion and rest are opposites. In other words, a body is at rest when its position, i.e., its coordinates, do not change with time. In other words, (Galilean) *rest* is defined as

$$\boldsymbol{x}(t) = \text{const}\,. \tag{10}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 46 Gottfried Leibniz (1646–1716)

We recall that $\boldsymbol{x}(t)$ is the abbreviation for the three coordinates $(x(t), y(t), z(t))$. Later we will see that this definition of rest, contrary to first impressions, is not much use and will have to be expanded. Nevertheless, any definition of rest implies that non-resting objects can be distinguished by comparing the rapidity of their displacement. Thus we can define the *velocity* $\boldsymbol{v}$ of an object as the change of its position $\boldsymbol{x}$ with time t. This is usually written as

$$\boldsymbol{v} = \frac{\mathrm{d}\boldsymbol{x}}{\mathrm{d}t} \,. \tag{11}$$

In this expression, valid for each coordinate separately, $\mathrm{d}/\mathrm{d}t$ means 'change with time'. We can thus say that velocity is the *derivative* of position with respect to time. The *speed* v is the name given to the magnitude of the velocity $\boldsymbol{v}$. Derivatives are written as fractions in order to remind the reader that they are derived from the idea of slope. The expression

$$\frac{\mathrm{d}s}{\mathrm{d}t} \quad \text{is meant as an abbreviation of} \quad \lim_{\Delta t \to 0} \frac{\Delta s}{\Delta t} \,, \tag{12}$$

a shorthand for saying that the *derivative at a point* is the limit of the secant slopes in the neighbourhood of the point, as shown in Figure 45. This definition implies the working rules

Challenge 127 e

$$\frac{\mathrm{d}(s+r)}{\mathrm{d}t} = \frac{\mathrm{d}s}{\mathrm{d}t} + \frac{\mathrm{d}r}{\mathrm{d}t} \quad , \quad \frac{\mathrm{d}(cs)}{\mathrm{d}t} = c\frac{\mathrm{d}s}{\mathrm{d}t} \quad , \quad \frac{\mathrm{d}}{\mathrm{d}t}\frac{\mathrm{d}s}{\mathrm{d}t} = \frac{\mathrm{d}^2 s}{\mathrm{d}t^2} \quad , \quad \frac{\mathrm{d}(sr)}{\mathrm{d}t} = \frac{\mathrm{d}s}{\mathrm{d}t}r + s\frac{\mathrm{d}r}{\mathrm{d}t} \,, \tag{13}$$

c being any number. This is all one ever needs to know about derivatives. Quantities such as $\mathrm{d}t$ and $\mathrm{d}s$, sometimes useful by themselves, are called *differentials*. These concepts are due to Gottfried Wilhelm Leibniz.* Derivatives lie at the basis of all calculations based on the continuity of space and time. Leibniz was the person who made it possible to describe and use velocity in physical formulae and, in particular, to use the idea of velocity at a given point in time or space for calculations.

The definition of velocity assumes that it makes sense to take the limit $\Delta t \to 0$. In other words, it is assumed that infinitely small time intervals do exist in nature. The definition

* Gottfried Wilhelm Leibniz (b. 1646 Leipzig, d. 1716 Hannover), Saxon lawyer, physicist, mathematician, philosopher, diplomat and historian. He was one of the great minds of mankind; he invented the differential calculus (before Newton) and published many influential and successful books in the various fields he explored, among them *De arte combinatoria*, *Hypothesis physica nova*, *Discours de métaphysique*, *Nouveaux essais sur l'entendement humain*, the *Théodicée* and the *Monadologia*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of velocity with derivatives is possible only because both space and time are described by sets which are *continuous*, or in mathematical language, *connected and complete*. In the rest of our walk we shall not forget that from the beginning of classical physics, *infinities* are present in its description of nature. The infinitely small is part of our definition of velocity. Indeed, differential calculus can be defined as the study of infinity and its uses. We thus discover that the appearance of infinity does not automatically render a description impossible or imprecise. In order to remain precise, physicists use only the smallest two of the various possible types of infinities. Their precise definition and an overview of other types are introduced in an upcoming chapter.

Page 825

The appearance of infinity in the usual description of motion was first criticized in his famous ironical arguments by Zeno of Elea (around 445 BCE), a disciple of Parmenides. In his so-called third argument, Zeno explains that since at every instant a given object occupies a part of space corresponding to its size, the notion of velocity at a given instant makes no sense; he provokingly concludes that therefore motion does not exist. Nowadays we would not call this an argument against the *existence* of motion, but against its usual *description*, in particular against the use of infinitely divisible space and time. (Do you agree?) Nevertheless, the description criticized by Zeno actually works quite well in everyday life. The reason is simple but deep: in daily life, changes are indeed continuous.

Ref. 53

Challenge 128 e

Large changes in nature are made up of many small changes. This property of nature is not obvious. For example, we note that we have tacitly assumed that the path of an object is not a fractal or some other badly behaved entity. In everyday life this is correct; in other domains of nature it is not. The doubts of Zeno will be partly rehabilitated later in our walk, and increasingly so the more we proceed. The rehabilitation is only partial, as the solution will be different from that which he envisaged; on the other hand, the doubts about the idea of 'velocity at a point' will turn out to be well-founded. For the moment though, we have no choice: we continue with the basic assumption that in nature changes happen smoothly.

Page 1401

Why is velocity necessary as a concept? Aiming for precision in the description of motion, we need to find the complete list of aspects necessary to specify the state of an object. The concept of velocity is obviously on this list.

Acceleration

Continuing along the same line, we call *acceleration* $\boldsymbol{a}$ of a body the change of velocity $\boldsymbol{v}$ with time, or

$$\boldsymbol{a} = \frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} = \frac{\mathrm{d}^2\boldsymbol{x}}{\mathrm{d}t^2} \,. \tag{14}$$

Acceleration is what we feel when the Earth trembles, an aeroplane takes off, or a bicycle goes round a corner. More examples are given in Table 13. Like velocity, acceleration has both a magnitude and a direction, properties indicated by the use of **bold** letters for their abbreviations. In short, acceleration, like velocity, is a vector quantity.

Acceleration is felt. The body is deformed and the sensors in our semicircular canals in the ear feel it. Higher accelerations can have stronger effects. For example, when accelerating a sitting person in the direction of the head at two or three times the value of usual gravitational acceleration, eyes stop working and the sight is greyed out, because

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 13 Some measured acceleration values

Observation	Acceleration
What is the lowest you can find?	Challenge 129 s
Back-acceleration of the galaxy M82 by its ejected jet	10 fm/s^2
Acceleration of a young star by an ejected jet	10 pm/s^2
Acceleration of the Sun in its orbit around the Milky Way	0.2 nm/s^2
Unexplained deceleration of the Pioneer satellites	0.8 nm/s^2
Centrifugal acceleration at Equator due to Earth's rotation	33 mm/s^2
Electron acceleration in household electricity wire due to alternating current	50 mm/s^2

Gravitational acceleration on the Earth's surface, depending on location	9.8 ± 0.1 m/s^2
Standard gravitational acceleration	9.806 65 m/s^2
Highest acceleration for a car or motorbike with engine-driven wheels	15 m/s^2
Space rockets at take-off	20 to 90 m/s^2
Acceleration of cheetah	32 m/s^2
Gravitational acceleration on Jupiter's surface	240 m/s^2
Acceleration of thrown stone	*c.* 120 m/s^2
Acceleration that triggers air bags in cars	360 m/s^2
Fastest leg-powered acceleration (by the froghopper, *Philaenus spumarius*, an insect)	4 km/s^2
Tennis ball against wall	0.1 Mm/s^2
Bullet acceleration in rifle	5 Mm/s^2
Fastest centrifuges	0.1 Gm/s^2
Acceleration of protons in large accelerator	90 Tm/s^2
Acceleration of protons inside nucleus	10^{31} m/s^2
Highest possible acceleration in nature	10^{52} m/s^2

the blood cannot reach the eye any more. Between 3 and 5g of continuous acceleration, or 7 to 9g of short time acceleration, consciousness is lost, because the brain does not receive enough blood, and blood may leak out of the feet or lower legs. High acceleration in the direction of the feet of a sitting person can lead to haemorrhagic strokes in the brain. The people most at risk are jet pilots; they have special clothes that send compressed air onto the pilot's bodies to avoid blood accumulating in the wrong places.

In a usual car, or on a motorbike, we can *feel* being accelerated. (These accelerations are below 1g and are therefore harmless.) Can you think of a situation where one is accelerated but does *not* feel it? Challenge 130 s

Higher derivatives than acceleration can also be defined in the same manner. They add little to the description of nature, because – as we will show shortly – neither these higher derivatives nor even acceleration itself are useful for the description of the state Challenge 131 s

Objects and point particles

> Wenn ich den Gegenstand kenne, so kenne ich auch sämtliche Möglichkeiten seines Vorkommens in Sachverhalten.*
>
> Ludwig Wittgenstein, *Tractatus*, 2.0123

One aim of the study of motion is to find a complete and precise description of both states and objects. With the help of the concept of space, the description of objects can be refined considerably. In particular, one knows from experience that all objects seen in daily life have an important property: they can be divided into *parts*. Often this observation is expressed by saying that all objects, or bodies, have two properties. First, they are made out of *matter*,** defined as that aspect of an object responsible for its impenetrability, i.e., the property preventing two objects from being in the same place. Secondly, bodies have a certain form or *shape*, defined as the precise way in which this impenetrability is distributed in space.

Challenge 132 e

In order to describe motion as accurately as possible, it is convenient to start with those bodies that are as simple as possible. In general, the smaller a body, the simpler it is. A body that is so small that its parts no longer need to be taken into account is called a *particle*. (The older term *corpuscle* has fallen out of fashion.) Particles are thus idealized small stones. The extreme case, a particle whose size is *negligible* compared with the dimensions of its motion, so that its position is described completely by a *single* triplet of coordinates, is called a *point particle* or a *point mass*. In equation (5), the stone was assumed to be such a point particle.

Do point-like objects, i.e., objects smaller than anything one can measure, exist in daily life? Yes and no. The most notable examples are the stars. At present, angular sizes as small as 2 μrad can be measured, a limit given by the fluctuations of the air in the atmosphere. In space, such as for the Hubble telescope orbiting the Earth, the angular limit is due to the diameter of the telescope and is of the order of 10 nrad. Practically all stars seen from Earth are smaller than that, and are thus effectively 'point-like', even when seen with the most powerful telescopes.

As an exception to the general rule, the size of a few large and nearby stars, of red giant type, can be measured with special instruments.*** Betelgeuse, the higher of the two shoulders of Orion shown in Figure 48, Mira in Cetus, Antares in Scorpio, Aldebaran in Taurus and Sirius in Canis Major are examples of stars whose size has been measured; they are all only a few light years from Earth. Of course, like the Sun, all other stars have a finite size, but one cannot prove this by measuring dimensions in photographs. (True?)

Ref. 55

Challenge 133 s

* 'If I know an object, then I also know all the possibilities of its occurrence in atomic facts.'

Ref. 54

** Matter is a word derived from the Latin 'materia', which originally meant 'wood' and was derived via intermediate steps from 'mater', meaning 'mother'.

*** The website www.astro.uiuc.edu/~kaler/sow/sowlist.html gives an introduction to the different types of stars. The www.astro.wisc.edu/~dolan/constellations website provides detailed and interesting information about constellations.

For an overview of the planets, see the beautiful book by K. R. Lang & C. A. Whitney, *Vagabonds de l'espace – Exploration et découverte dans le système solaire*, Springer Verlag, 1993. The most beautiful pictures of the stars can be found in D. Malin, *A View of the Universe*, Sky Publishing and Cambridge University Press, 1993.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

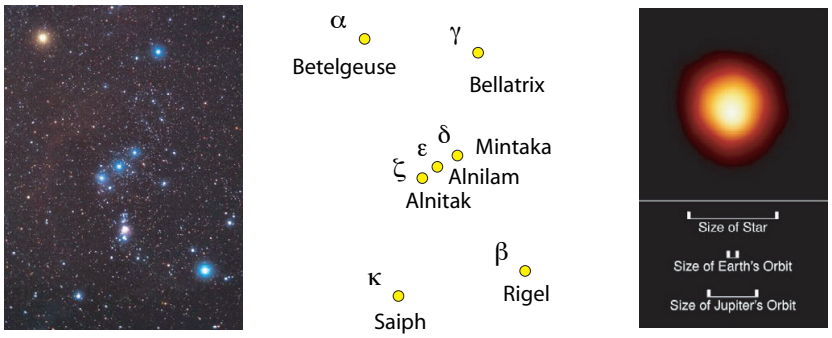

FIGURE 48 Orion in natural colours (© Matthew Spinelli) and Betelgeuse (ESA, NASA)

The difference between 'point-like' and finite size sources can be seen with the naked eye: at night, stars twinkle, but planets do not. (Check it!) This effect is due to the turbulence of air. Turbulence has an effect on the almost point-like stars because it deflects light rays by small amounts. On the other hand, air turbulence is too weak to lead to twinkling of sources of larger angular size, such as planets or artificial satellites,* because the deflection is averaged out in this case.

Challenge 134 e

An object is *point-like for the naked eye* if its angular size is smaller than about $2' = 0.6$ mrad. Can you estimate the size of a 'point-like' dust particle? By the way, an object is *invisible* to the naked eye if it is point-like *and* if its luminosity, i.e., the intensity of the light from the object reaching the eye, is below some critical value. Can you estimate whether there are any man-made objects visible from the Moon, or from the space shuttle?

Challenge 135 s

Challenge 136 s

The above definition of 'point-like' in everyday life is obviously misleading. Do proper, real point particles exist? In fact, is it at all possible to show that a particle has vanishing size? This question will be central in the last two parts of our walk. In the same way, we need to ask and check whether points in space do exist. Our walk will lead us to the astonishing result that all the answers to these questions are negative. Can you imagine why? Do not be disappointed if you find this issue difficult; many brilliant minds have had the same problem.

Challenge 137 s

However, many particles, such as electrons, quarks or photons are point-like for all practical purposes. Once one knows how to describe the motion of point particles, one can also describe the motion of extended bodies, rigid or deformable, by assuming that they are made of parts. This is the same approach as describing the motion of an animal as a whole by combining the motion of its various body parts. The simplest description, the *continuum approximation*, describes extended bodies as an infinite collection of point particles. It allows us to understand and to predict the motion of milk and honey, the motion of the air in hurricanes and of perfume in rooms. The motion of fire and all other gaseous bodies, the bending of bamboo in the wind, the shape changes of chewing gum, and the growth of plants and animals can also be described in this way.

Ref. 56

A more precise description than the continuum approximation is given below. Nev-

Page 976

* A *satellite* is an object circling a planet, like the Moon; an *artificial satellite* is a system put into orbit by humans, like the Sputniks.

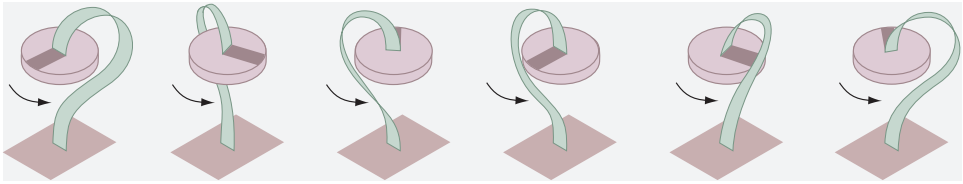

FIGURE 49 How an object can rotate continuously without tangling up the connection to a second object

ertheless, all observations so far have confirmed that the motion of large bodies can be described to high precision as the result of the motion of their parts. This approach will guide us through the first two parts of our mountain ascent. Only in the final part will we discover that, at a fundamental scale, this decomposition is impossible.

Legs and wheels

The parts of a body determine its shape. Shape is an important aspect of bodies: among other things, it tells us how to count them. In particular, living beings are always made of a single body. This is not an empty statement: from this fact we can deduce that animals cannot have wheels or propellers, but only legs, fins, or wings. Why?

Living beings have only one surface; simply put, they have only one piece of skin. Appendix B Mathematically speaking, animals are *connected*. Ref. 57 This is often assumed to be obvious, and it is often mentioned that the blood supply, the nerves and the lymphatic connections to a rotating part would get tangled up. However, this argument is not so simple, as Figure 49 shows. It shows that it is indeed possible to rotate a body continuously against a second one, without tangling up the connections. Can you find an example for this kind of motion in your own body? Challenge 138 s Are you able to see how many cables may be attached to the rotating body of the figure without hindering the rotation? Challenge 139 s

Despite the possibility of animals having rotating parts, the method of Figure 49 still cannot be used to make a practical wheel or propeller. Challenge 140 s Can you see why? Evolution had no choice: it had to avoid animals with parts rotating around axles. That is the reason that propellers and wheels do not exist in nature. Of course, this limitation does not rule out Ref. 58 that living bodies move by rotation as a whole: tumbleweed, seeds from various trees, some insects, certain other animals, children and dancers occasionally move by rolling or rotating as a whole.

Single bodies, and thus all living beings, can only move through *deformation* of their shape: therefore they are limited to walking, running, rolling, crawling or flapping wings or fins. Ref. 59 Extreme examples of leg use in nature are shown in Figure 50; rolling spiders that use their legs to steer the rolling have also been found recently. Walking on water is shown in Figure 100 on page 140; examples of wings are given in Figure 573 on page 1305. In contrast, systems of several bodies, such as bicycles, pedal boats or other machines, can move *without* any change of shape of their components, thus enabling the use of axles with wheels, propellers or other rotating devices.*

* Despite the disadvantage of not being able to use rotating parts and of being restricted to one piece only, nature's moving constructions, usually called animals, often outperform human built machines. As an ex-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 50 'Wheels' and legs in living beings: the rolling shrimp *Nannosquilla decemspinosa* (2 cm body length, 1.5 rotations per second, up to 2 m, can even roll slightly uphill slopes), the rolling caterpillar *Pleurotya ruralis* (can only roll downhill, to escape predators), the Red millipede *Aphistogoniulus erythrocephalus* (15 cm body length) and a Gekko on a glass pane (15 cm body length) (© Robert Full, John Brackenbury / Science Photo Library, David Parks and Marcel Berendsen)

In summary, whenever we observe a construction in which some part is turning continuously (and without the 'wiring' of the figure) we know immediately that it is an artefact: it is a machine, not a living being (but built by one). However, like so many statements about living creatures, this one also has exceptions. The distinction between one and two bodies is poorly defined if the whole system is made of only a few molecules. This happens most clearly inside bacteria. Organisms such as *Escherichia coli*, the well-known bacterium found in the human gut, or bacteria from the *Salmonella* family, all swim using flagella. *Flagella* are thin filaments, similar to tiny hairs that stick out of the cell membrane. In the 1970s it was shown that each flagellum, made of one or a few long molecules with a diameter of a few tens of nanometres, does in fact turn about its axis. A bacterium is able to turn its flagella in both clockwise and anticlockwise directions, can achieve more than 1000 turns per second, and can turn all its flagella in perfect synchronization. (These wheels are so tiny that they do not need a mechanical connection.) Therefore wheels actually do exist in living beings, albeit only tiny ones. But let us now continue with our study of simple objects.

Page 1307

Ref. 60

ample, compare the size of the smallest flying systems built by evolution with those built by humans. (See, e.g. pixelito.reference.be.) There are two reasons for this discrepancy. First, nature's systems have integrated repair and maintenance systems. Second, nature can build large structures inside containers with small openings. In fact, nature is very good at what people do when they build sailing ships inside glass bottles. The human body is full of such examples; can you name a few?

Challenge 146 e or if it does not?

* *

The level of acceleration a human can survive depends on the duration over which one is subjected to it. For a tenth of a second, $30\,g = 300\,\mathrm{m/s^2}$, as generated by an ejector seat in an aeroplane, is acceptable. (It seems that the record acceleration a human has survived is about $80\,g = 800\,\mathrm{m/s^2}$.) But as a rule of thumb it is said that accelerations of $15\,g = 150\,\mathrm{m/s^2}$ or more are fatal.

* *

The highest *microscopic* accelerations are observed in particle collisions, where one gets values up to $10^{35}\,\mathrm{m/s^2}$. The highest *macroscopic* accelerations are probably found in the collapsing interiors of *supernovae*, exploding stars which can be so bright as to be visible in the sky even during the daytime. A candidate on Earth is the interior of collapsing bubbles in liquids, a process called *cavitation*. Cavitation often produces light, an effect Ref. 61 discovered by Frenzel and Schulte in 1934 and called *sonoluminescence*. (See Figure 94.) It appears most prominently when air bubbles in water are expanded and contracted by underwater loudspeakers at around 30 kHz and allows precise measurements of bubble motion. At a certain threshold intensity, the bubble radius changes at 1500 m/s in as little Ref. 62 as a few μm, giving an acceleration of several $10^{11}\,\mathrm{m/s^2}$.

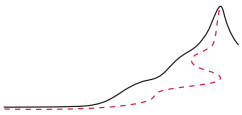
* *

Legs are easy to build. Nature has even produced a millipede, *Illacme plenipes*, that has 750 legs. The animal is 3 to 4 cm long and about 0.5 mm wide. This seems to be the record so far.

Summary of kinematics

The description of everyday motion of mass points with three coordinates as $(x(t), y(t), z(t))$ is simple, precise and complete. It assumes that objects can be followed along there paths. Therefore, the description does not work for an important case: the motion of images.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 4

FROM OBJECTS AND IMAGES TO CONSERVATION

Walking through a forest we observe two rather different types of motion: the breeze moves the leaves, and at the same time their shadows move on the ground. Shadows Ref. 63 are a simple type of image. Both objects and images are able to move. Running tigers, falling snowflakes, and material ejected by volcanoes are examples of motion, since they all change position over time. For the same reason, the shadow following our body, the beam of light circling the tower of a lighthouse on a misty night, and the rainbow that constantly keeps the same apparent distance from the hiker are examples of motion.

Everybody who has ever seen an animated cartoon knows that images can move in more surprising ways than objects. Images can change their size, shape and even colour, a feat only few objects are able to perform.* Images can appear and disappear without trace, multiply, interpenetrate, go backwards in time and defy gravity or any other force. Images, even ordinary shadows, can move faster than light. Images can float in space and keep the same distance from approaching objects. Objects can do almost none of Ref. 65 this. In general, the 'laws of cartoon physics' are rather different from those in nature. In fact, the motion of images does not seem to follow any rules, in contrast to the motion of objects. On the other hand, both objects and images differ from their environment in that they have *boundaries* defining their size and shape. We feel the need for precise criteria allowing the two cases to be distinguished.

Making a clear distinction between images and objects is performed using the same method that children or animals use when they stand in front of a mirror for the first time: they try to *touch* what they see. Indeed, if we are able to touch what we see – or more precisely, if we are able to move it – we call it an *object*, otherwise an *image*.** Page 1071 Images cannot be touched, but objects can. Images cannot hit each other, but objects can. And as everybody knows, touching something means feeling that it resists movement.

* Excluding very slow changes such as the change of colour of leaves in the Fall, in nature only certain crystals, the octopus, the chameleon and a few other animals achieve this. Of man-made objects, television, Challenge 147 s computer displays, heated objects and certain lasers can do it. Do you know more examples? An excellent source of information on the topic of colour is the book by K. Nassau, *The Physics and Chemistry of Colour – the fifteen causes of colour*, J. Wiley & Sons, 1983. In the popular science domain, the most beautiful book is the classic work by the Flemish astronomer Marcel G. J. Minnaert, *Light and Colour in the Outdoors*, Springer, 1993, an updated version based on his wonderful book series, *De natuurkunde van 't vrije veld*, Ref. 64 Thieme & Cie, 1937. Reading it is a must for all natural scientists. On the web, there is also the – simpler, but excellent – webexhibits.org/causesofcolour website.

** One could propose including the requirement that objects may be rotated; however, this requirement gives difficulties in the case of atoms, as explained on page 1039, and with elementary particles, so that rotation is not made a separate requirement.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

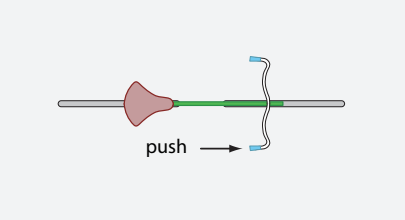


FIGURE 52 In which direction does the bicycle turn?

Certain bodies, such as butterflies, pose little resistance and are moved with ease, others, such as ships, resist more, and are moved with more difficulty. This resistance to motion – more precisely, to change of motion – is called *inertia*, and the difficulty with which a body can be moved is called its *(inertial) mass*. Images have neither inertia nor mass.

Summing up, for the description of motion we must distinguish bodies, which can be touched and are impenetrable, from images, which cannot and are not. Everything visible is either an object or an image; there is no third possibility. (Do you agree?) If the object is so far away that it cannot be touched, such as a star or a comet, it can be difficult to decide whether one is dealing with an image or an object; we will encounter this difficulty repeatedly. For example, how would you show that comets are objects and not images, as Galileo claimed?

Challenge 148 s

Challenge 149 s

In the same way that objects are made of *matter*, images are made of *radiation*. Images are the domain of shadow theatre, cinema, television, computer graphics, belief systems and drug experts. Photographs, motion pictures, ghosts, angels, dreams and many hallucinations are images (sometimes coupled with brain malfunction). To understand images, we need to study radiation (plus the eye and the brain). However, due to the importance of objects – after all we are objects ourselves – we study the latter first.

Ref. 66

Motion and contact

> “Democritus affirms that there is only one type of movement: That resulting from collision.”
>
> Aetius, *Opinions*.

Ref. 67

When a child rides a monocycle, she or he makes use of a general rule in our world: one body acting on another puts it in motion. Indeed, in about six hours, anybody can learn to ride and enjoy a monocycle. As in all of life's pleasures, such as toys, animals, women, machines, children, men, the sea, wind, cinema, juggling, rambling and loving, something pushes something else. Thus our first challenge is to describe this transfer of motion in more precise terms.

Contact is not the only way to put something into motion; a counter-example is an apple falling from a tree or one magnet pulling another. Non-contact influences are more fascinating: nothing is hidden, but nevertheless something mysterious happens. Contact motion seems easier to grasp, and that is why one usually starts with it. However, despite this choice, non-contact forces are not easily avoided. Taking this choice one has a similar experience to that of cyclists. (See Figure 52.) If you ride a bicycle at a sustained speed and try to turn left by pushing the right-hand steering bar, you will turn *right*. By the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

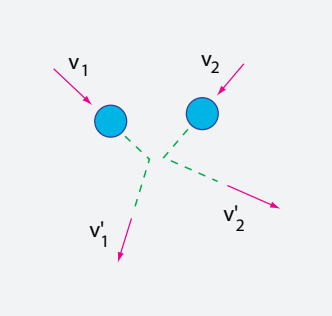

FIGURE 53 Collisions define mass

FIGURE 54 The standard kilogram (© BIPM)

way, this surprising effect, also known to motor bike riders, obviously works only above a certain minimal speed. Can you determine what this speed is? Be careful! Too strong a push will make you fall. Challenge 150 s

Something similar will happen to us as well; despite our choice for contact motion, the rest of our walk will rapidly force us to study non-contact interactions.

What is mass?

> Δός μοι ποῦ στω καὶ κινῶ τὴν γῆν.
> Da ubi consistam, et terram movebo.*
>
> Archimedes

When we push something we are unfamiliar with, such as when we kick an object on the street, we automatically pay attention to the same aspect that children explore when they stand in front of a mirror for the first time, or when they see a red laser spot for the first time. They check whether the unknown entity can be pushed, and they pay attention to how the unknown object moves under their influence. The high precision version of the experiment is shown in Figure 53. Repeating the experiment with various pairs of objects, we find – as in everyday life – that a fixed quantity m_i can be ascribed to every object i. The more difficult it is to move an object, the higher the quantity; it is determined by the relation

$$\frac{m_2}{m_1} = -\frac{\Delta v_1}{\Delta v_2} \tag{15}$$

* 'Give me a place to stand, and I'll move the Earth.' Archimedes (*c.* 283–212), Greek scientist and engineer. This phrase was attributed to him by Pappus. Already Archimedes knew that the distinction used by lawyers between movable and immovable property made no sense. Ref. 68

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 55 Antoine Lavoisier (1743–1794) and his wife

where Δv is the velocity change produced by the collision. The number m_i is called the *mass* of the object i.

In order to have mass values that are common to everybody, the mass value for one particular, selected object has to be fixed in advance. This special object, shown in Figure 54 is called the *standard kilogram* and is kept with great care under vacuum in a glass container in Sèvres near Paris. It is touched only once every few years because otherwise dust, humidity, or scratches would change its mass. Through the standard kilogram the value of the mass of every other object in the world is determined.

The mass thus measures the difficulty of getting something moving. High masses are harder to move than low masses. Obviously, only objects have mass; images don't. (By the way, the word 'mass' is derived, via Latin, from the Greek μαζα – bread – or the Hebrew 'mazza' – unleavened bread. That is quite a change in meaning.)

Ref. 54

Experiments with everyday life objects also show that throughout any collision, the sum of all masses is *conserved*:

$$\sum_i m_i = \text{const} \,. \tag{16}$$

The principle of conservation of mass was first stated by Antoine-Laurent Lavoisier.* Conservation of mass also implies that the mass of a composite system is the sum of the mass of the components. In short, *Galilean mass is a measure for the quantity of matter.*

* Antoine-Laurent Lavoisier (1743–1794), French chemist and a genius. Lavoisier was the first to understand that combustion is a reaction with oxygen; he discovered the components of water and introduced mass measurements into chemistry. There is a good, but most probably false story about him: When he was (unjustly) sentenced to the guillotine during the French revolution, he decided to use the situations for a scientific experiment. He would try to blink his eyes as frequently as possible after his head was cut off, in order to show others how long it takes to lose consciousness. Lavoisier managed to blink eleven times. It is unlcear whether the story is true or not. It is known, however, that it could be true. Indeed, if a decapitated has no pain or shock, he can remain conscious for up to half a minute.

FIGURE 56 Christiaan Huygens (1629–1695)

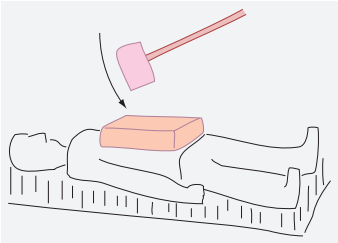

FIGURE 57 Is this dangerous?

Momentum and mass

The definition of mass can also be given in another way. We can ascribe a number m_i to every object i such that for collisions free of outside interference the following sum is unchanged *throughout* the collision:

$$\sum_i m_i \boldsymbol{v}_i = \text{const} \,. \tag{17}$$

The product of the velocity $\boldsymbol{v}_i$ and the mass m_i is called the *momentum* of the body. The sum, or *total momentum* of the system, is the same before and after the collision; momentum is a *conserved* quantity. *Momentum conservation defines mass.* The two conservation principles (16) and (17) were first stated in this way by the important Dutch physicist Christiaan Huygens.* Momentum and mass are conserved in everyday motion of objects. Neither quantity can be defined for the motion of images. Some typical momentum values are given in Table 15.

Momentum conservation implies that when a moving sphere hits a resting one of the same mass and without loss of energy, a simple rule determines the angle between the directions the two spheres take after the collision. Can you find this rule? It is particularly useful when playing billiards. We will find out later that it is *not* valid in special relativity.

Challenge 151 s

Another consequence of momentum conservation is shown in Figure 57: a man is

* Christiaan Huygens (b. 1629 's Gravenhage, d. 1695 Hofwyck) was one of the main physicists and mathematicians of his time. Huygens clarified the concepts of mechanics; he also was one of the first to show that light is a wave. He wrote influential books on probability theory, clock mechanisms, optics and astronomy. Among other achievements, Huygens showed that the Orion Nebula consists of stars, discovered Titan, the moon of Saturn, and showed that the rings of Saturn consist of rock. (This is in contrast to Saturn itself, whose density is lower than that of water.)

lying on a bed of nails with a large block of concrete on his stomach. Another man is hitting the concrete with a heavy sledgehammer. As the impact is mostly absorbed by the concrete, there is no pain and no danger – unless the concrete is missed. Why? Challenge 152 s

The above definition of mass has been generalized by the physicist and philosopher Ernst Mach* in such a way that it is valid even if the two objects interact without contact, as long as they do so along the line connecting their positions. The mass ratio between two bodies is defined as a negative inverse acceleration ratio, thus as

$$\frac{m_2}{m_1} = -\frac{a_1}{a_2} \,, \tag{18}$$

where a is the acceleration of each body during the interaction. This definition has been studied in much detail in the physics community, mainly in the nineteenth century. A few points sum up the results:

— The definition of mass *implies* the conservation of total momentum $\sum mv$. Momentum conservation is *not* a separate principle. Conservation of momentum cannot be checked experimentally, because mass is defined in such a way that the principle holds.

* Ernst Mach (1838 Chrlice–1916 Vaterstetten), Austrian physicist and philosopher. The *mach* unit for aeroplane speed as a multiple of the speed of sound in air (about 0.3 km/s) is named after him. He developed the so-called Mach–Zehnder interferometer; he also studied the basis of mechanics. His thoughts about mass and inertia influenced the development of general relativity, and led to Mach's principle, which will appear later on. He was also proud to be the last scientist denying – humorously, and against all evidence – the existence of atoms.

— The definition of mass *implies* the equality of the products $m_1 a_1$ and $-m_2 a_2$. Such products are called *forces*. The equality of acting and reacting forces is not a separate principle; mass is defined in such a way that the principle holds.
— The definition of mass is *independent* of whether contact is involved or not, and whether the origin of the accelerations is due to electricity, gravitation, or other interactions.* Since the interaction does not enter the definition of mass, mass values defined with the help of the electric, nuclear or gravitational interaction all agree, as long as momentum is conserved. All known interactions conserve momentum. For some unfortunate historical reasons, the mass value measured with the electric or nuclear interactions is called the 'inertial' mass and the mass measured using gravity is called the 'gravitational' mass. As it turns out, this artificial distinction has no real meaning; this becomes especially clear when one takes an observation point that is far away from all the bodies concerned.
— The definition of mass requires observers at rest or in inertial motion.

By measuring the masses of bodies around us, as given in Table 16, we can explore the science and art of experiments. We also discover the main properties of mass. It is *additive* in everyday life, as the mass of two bodies combined is equal to the sum of the two separate masses. Furthermore, mass is *continuous*; it can seemingly take any positive value. Finally, mass is *conserved*; the mass of a system, defined as the sum of the mass of all constituents, does not change over time if the system is kept isolated from the rest of the world. Mass is not only conserved in collisions but also during melting, evaporation, digestion and all other processes.

Later we will find that in the case of mass all these properties, summarized in Table 17, are only approximate. Precise experiments show that none of them are correct.** For the moment we continue with the present, Galilean concept of mass, as we have not yet a better one at our disposal.

In a famous experiment in the sixteenth century, for several weeks Santorio Santorio (Sanctorius) (1561–1636), friend of Galileo, lived with all his food and drink supply, and also his toilet, on a large balance. He wanted to test mass conservation. How did the measured weight change with time? Challenge 154 s

The definition of mass through momentum conservation implies that when an object falls, the Earth is accelerated upwards by a tiny amount. If one could measure this tiny amount, one could determine the mass of the Earth. Unfortunately, this measurement is impossible. Can you find a better way to determine the mass of the Earth? Challenge 155 s

Summarizing Table 17, the mass of a body is thus most precisely described by a *positive* real number, often abbreviated m or M. This is a direct consequence of the impenetrability of matter. Indeed, a *negative* (inertial) mass would mean that such a body would move in the opposite direction of any applied force or acceleration. Such a body could not be kept in a box; it would break through any wall trying to stop it. Strangely enough, nega-

* As mentioned above, only *central* forces obey the relation (18) used to define mass. Central forces act between the centre of mass of bodies. We give a precise definition later. However, since all fundamental forces are central, this is not a restriction. There seems to be one notable exception: magnetism. Is the definition of mass valid in this case? Page 105 Challenge 153 s

** In particular, in order to define mass we must be able to *distinguish* bodies. This seems a trivial requirement, but we discover that this is not always possible in nature.

Our galaxy's visible mass	$3 \cdot 10^{41}$ kg
Our galaxy's estimated total mass	$2 \cdot 10^{42}$ kg
virgo supercluster	$2 \cdot 10^{46}$ kg
Total mass visible in the universe	10^{54} kg

tive mass bodies would still fall downwards in the field of a large positive mass (though more slowly than an equivalent positive mass). Are you able to confirm this? Challenge 156 e However, a small positive mass object would float away from a large negative-mass body, as you can easily deduce by comparing the various accelerations involved. A positive and a negative mass of the same value would stay at constant distance and spontaneously accelerate away along the line connecting the two masses. Challenge 157 e Note that both energy and momentum are conserved in all these situations.* Negative-mass bodies have never been observed.

* For more curiosities, see R. H. PRICE, Negative mass can be positively amusing, *American Journal of Physics* **61**, pp. 216–217, 1993. Negative mass particles in a box would heat up a box made of positive mass while traversing its walls, and accelerating, i.e., losing energy, at the same time. Page 99 They would allow one to build a *perpetuum mobile* of the second kind, i.e., a device circumventing the second principle of thermodynamics. Challenge 158 e Moreover, such a system would have no thermodynamic equilibrium, because its energy could

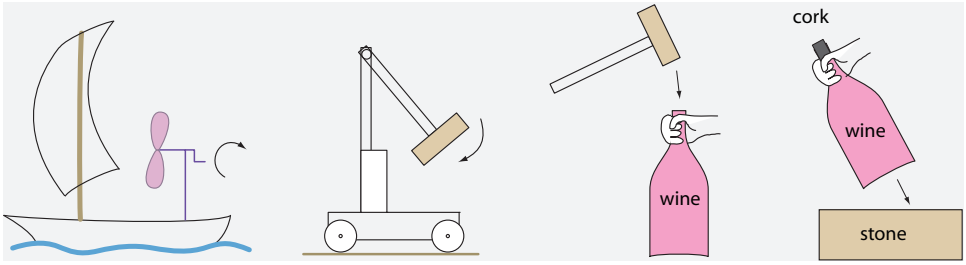

FIGURE 59 What happens in these four situations?

Is motion eternal? – Conservation of momentum

> Every body continues in the state of rest or of uniform motion in a straight line except in so far as it doesn't.
>
> Arthur Eddington*

The product $\boldsymbol{p} = m\boldsymbol{v}$ of mass and velocity is called the *momentum* of a particle; it describes the tendency of an object to keep moving during collisions. The larger it is, the harder it is to stop the object. Like velocity, momentum has a direction and a magnitude: it is a vector. In French, momentum is called 'quantity of motion', a more appropriate term. In the old days, the term 'motion' was used instead of 'momentum', for example by Newton. Relation (17), the conservation of momentum, therefore expresses the conservation of motion during interactions.

Momentum, like energy is an *extensive quantity*. That means that it can be said that both *flow* from one body to the other, and that they can be *accumulated* in bodies, in the same way that water flows and can be accumulated in containers. Imagining momentum as something that can be *exchanged* between bodies in collisions is always useful when thinking about the description of moving objects.

Momentum is conserved. That explains the limitations you might experience when being on a perfectly frictionless surface, such as ice or a polished, oil covered marble: you cannot propel yourself forward by patting your own back. (Have you ever tried to put a cat on such a marble surface? It is not even able to stand on its four legs. Neither
Challenge 160 s are humans. Can you imagine why?) Momentum conservation also answers the puzzles of Figure 59.

The conservation of momentum and mass also means that teleportation ('beam me
Challenge 161 s up') is impossible in nature. Can you explain this to a non-physicist?

Momentum conservation implies that momentum can be imagined to be like an invisible fluid. In an interaction, the invisible fluid is transferred from one object to another. However, the sum is always constant.

Momentum conservation implies that motion never stops; it is only *exchanged*. On the other hand, motion often 'disappears' in our environment, as in the case of a stone dropped to the ground, or of a ball left rolling on grass. Moreover, in daily life we often observe the creation of motion, such as every time we open a hand. How do these

* Arthur Eddington (1882–1944), British astrophysicist.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

examples fit with the conservation of momentum?

It turns out that the answer lies in the microscopic aspects of these systems. A muscle only *transforms* one type of motion, namely that of the electrons in certain chemical compounds* into another, the motion of the fingers. The working of muscles is similar to that of a car engine transforming the motion of electrons in the fuel into motion of the wheels. Both systems need fuel and get warm in the process.

We must also study the microscopic behaviour when a ball rolls on grass until it stops. The disappearance of motion is called *friction*. Studying the situation carefully, one finds that the grass and the ball heat up a little during this process. During friction, visible motion is transformed into heat. Later, when we discover the structure of matter, it will become clear that heat is the disorganized motion of the microscopic constituents of every material. When these constituents all move in the same direction, the object as a whole moves; when they oscillate randomly, the object is at rest, but is warm. Heat is a form of motion. Friction thus only seems to be disappearance of motion; in fact it is a transformation of ordered into unordered motion.

Despite momentum conservation, *macroscopic* perpetual motion does not exist, since friction cannot be completely eliminated.** Motion is eternal only at the microscopic scale. In other words, the disappearance and also the spontaneous appearance of motion in everyday life is an illusion due to the limitations of our senses. For example, the motion proper of every living being exists before its birth, and stays after its death. The same happens with its energy. This result is probably the closest one can get to the idea of everlasting life from evidence collected by observation. It is perhaps less than a coincidence that energy used to be called *vis viva*, or 'living force', by Leibniz and many others.

Since motion is conserved, it has no origin. Therefore, at this stage of our walk we cannot answer the fundamental questions: Why does motion exist? What is its origin? The end of our adventure is nowhere near.

More conservation – energy

When collisions are studied in detail, a second conserved quantity turns up. Experiments show that in the case of perfect, or elastic collisions – collisions without friction – the

Ref. 70

* Usually adenosine triphosphate (ATP), the fuel of most processes in animals.

** Some funny examples of past attempts to built a *perpetual motion machine* are described in Stanislav Michel, *Perpetuum mobile*, VDI Verlag, 1976. Interestingly, the idea of eternal motion came to Europe from India, via the Islamic world, around the year 1200, and became popular as it opposed the then standard view that all motion on Earth disappears over time. See also the web.archive.org/web/20040812085618/http://www.geocities.com/mercutio78_99/pmm.html and the www.lhup.edu/~dsimanek/museum/unwork.htm websites. The conceptual mistake made by eccentrics and used by crooks is always the same: the hope of overcoming friction. (In fact, this applied only to the perpetual motion machines of the second kind; those of the first kind – which are even more in contrast with observation – even try to generate energy from nothing.)

Ref. 71

If the machine is well constructed, i.e., with little friction, it can take the little energy it needs for the sustenance of its motion from very subtle environmental effects. For example, in the Victoria and Albert Museum in London one can admire a beautiful clock powered by the variations of air pressure over time.

Challenge 162 s

Low friction means that motion takes a long time to stop. One immediately thinks of the motion of the planets. In fact, there *is* friction between the Earth and the Sun. (Can you guess one of the mechanisms?) But the value is so small that the Earth has already circled around the Sun for thousands of millions of years, and will do so for quite some time more.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 60 Robert Mayer (1814–1878)

following quantity, called the *kinetic energy* T of the system, is also conserved:

$$T = \sum_i \tfrac{1}{2} m_i \boldsymbol{v}_i^2 = \sum_i \tfrac{1}{2} m_i v_i^2 = \text{const} \,. \tag{19}$$

Kinetic energy is the ability that a body has to induce change in bodies it hits. Kinetic energy thus depends on the mass and on the square of the speed v of a body. The full name 'kinetic energy' was introduced by Gustave-Gaspard Coriolis.*

Energy is a word taken from ancient Greek; originally it was used to describe character, and meant 'intellectual or moral vigour'. It was taken into physics by Thomas Young (1773–1829) in 1807 because its literal meaning is 'force within'. (The letters E, W, A and several others are also used to denote energy.) Another, equivalent definition of energy will become clear later: energy is what can be transformed into heat.

(Physical) *energy* is the measure of the ability to generate motion. A body has a lot of energy if it has the ability to move many other bodies. Energy is a single number; it has no direction. The total momentum of two equal masses moving with opposite velocities is zero; their total energy increases with velocity. Energy thus also measures motion, but in a different way than momentum. Energy measures motion in a more global way. An equivalent definition is the following. Energy is the ability to perform work. Here, the physical concept of work is just the precise version of what is meant by work in everyday life.**

Do not be surprised if you do not grasp the difference between momentum and energy straight away: physicists took about two centuries to figure it out. For some time they even insisted on using the same word for both, and often they didn't know which situation required which concept. So you are allowed to take a few minutes to get used to it.

Both energy and momentum measure how systems change. Momentum tells how systems change over distance, energy measures how systems change over time. Momentum is needed to compare motion here and there. Energy is needed to compare motion now and later. Some measured energy values are given in Table 19.

One way to express the difference between energy and momentum is to think about the following challenges. Is it more difficult to stop a running man with mass m and

* Gustave-Gaspard Coriolis (b. 1792 Paris, d. 1843 Paris), French engineer and mathematician. He introduced the modern concepts of 'work' and of 'kinetic energy', and discovered the Coriolis effect. Coriolis also introduced the factor 1/2, in order that the relation $\mathrm{d}T/\mathrm{d}v = p$ would be obeyed. (Why?)

Challenge 163 s

** (Physical) *work* is the product of force and distance in direction of the force.

Rotation energy of Earth	$2 \cdot 10^{29}$ J
Supernova explosion	10^{44} J
Gamma ray burst	up to 10^{47} J
Energy content $E = mc^2$ of Sun's mass	$1.8 \cdot 10^{47}$ J
Energy content of Galaxy's central black hole	$4 \cdot 10^{53}$ J

Challenge 164 e speed v, or one with mass $m/2$ and speed $2v$, or one with mass $m/2$ and speed $\sqrt{2}v$? You may want to ask a rugby-playing friend for confirmation.

Another distinction is illustrated by athletics: the *real* long jump world record, almost 10 m, is still kept by an athlete who in the early twentieth century ran with two weights in his hands, and then threw the weights behind him at the moment he took off. Can you Challenge 165 s explain the feat?

When a car travelling at 100 m/s runs head-on into a parked car of the same kind and Challenge 166 s make, which car receives the greatest damage? What changes if the parked car has its

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

brakes on?

To get a better feeling for energy, here is an additional approach. The world consumption of energy by human machines (coming from solar, geothermal, biomass, wind, nuclear, hydro, gas, oil, coal, or animal sources) in the year 2000 was about 420 EJ,* for a world population of about 6000 million people. To see what this energy consumption means, we translate it into a personal power consumption; we get about 2.2 kW. The watt W is the unit of power, and is simply defined as 1 W = 1 J/s, reflecting the definition of *(physical) power* as energy used per unit time. (The precise wording is: power is energy flowing per time through a defined closed surface.) As a working person can produce mechanical work of about 100 W, the average human energy consumption corresponds to about 22 humans working 24 hours a day. (See Table 20 for some power values found in nature.) In particular, if we look at the energy consumption in First World countries, the average inhabitant there has machines working for them equivalent to several hundred 'servants'. Can you point out some of these machines?

Ref. 72

Challenge 167 s

Kinetic energy is thus not conserved in everyday life. For example, in non-elastic collisions, such as that of a piece of chewing gum hitting a wall, kinetic energy is lost. *Friction* destroys kinetic energy. At the same time, friction produces heat. It was one of the important conceptual discoveries of physics that *total* energy is conserved if one includes the discovery that heat is a form of energy. Friction is thus in fact a process transforming kinetic energy, i.e., the energy connected with the motion of a body, into heat. On a microscopic scale, energy is conserved.** Indeed, without energy conservation, the concept of time would not be definable. We will show this connection shortly.

In summary, in addition to mass and energy, everyday linear motion also conserves energy. To discover the last conserved quantity, we explore another type of motion.

Rotation

Rotation keeps us alive. Without the change of day and night, we would be either fried or frozen to death, depending on our location on our planet. A short exploration of rotation is thus appropriate.

All objects have the ability to rotate. We saw before that a body is described by its reluctance to move; similarly, a body also has a reluctance to turn. This quantity is called its *moment of inertia* and is often abbreviated Θ – pronounced 'theta'. The speed or rate of rotation is described by *angular velocity*, usually abbreviated ω – pronounced 'omega'. A few values found in nature are given in Table 22.

The observables that describe rotation are similar to those describing linear motion, as shown in Table 23. Like mass, the moment of inertia is defined in such a way that the

Page 909

* For the explanation of the abbreviation E, see Appendix C.

** In fact, the conservation of energy was stated in its full generality in public only in 1842, by Julius Robert Mayer. He was a medical doctor by training, and the journal *Annalen der Physik* refused to publish his paper, as it supposedly contained 'fundamental errors'. What the editors called errors were in fact mostly – but not only – contradictions of their prejudices. Later on, Helmholtz, Thomson-Kelvin, Joule and many others acknowledged Mayer's genius. However, the first to have stated energy conservation in its modern form was the French physicist Sadi Carnot (1796–1832) in 1820. To him the issue was so clear that he did not publish the result. In fact he went on and discovered the second 'law' of thermodynamics. Today, energy conservation, also called the first 'law' of thermodynamics, is one of the pillars of physics, as it is valid in all its domains.

Sun's output	384.6 YW
Maximum power in nature, $c^5/4G$	$9.1 \cdot 10^{51}$ W

sum of *angular momenta* L – the product of moment of inertia and angular velocity – is conserved in systems that do not interact with the outside world:

$$\sum_i \Theta_i \boldsymbol{\omega}_i = \sum_i \boldsymbol{L}_i = \text{const} \,. \tag{20}$$

In the same way that the conservation of linear momentum defines mass, the conservation of angular momentum defines the moment of inertia.

The moment of inertia can be related to the mass and shape of a body. If the body is

value of the moment of inertia depends on the location of the axis used for its definition. For each axis direction, one distinguishes an *intrinsic* moment of inertia, when the axis passes through the centre of mass of the body, from an *extrinsic* moment of inertia, when it does not.* In the same way, one distinguishes intrinsic and extrinsic angular momenta. (By the way, the *centre of mass* of a body is that imaginary point which moves straight during vertical fall, even if the body is rotating. Can you find a way to determine its location for a specific body?)

Challenge 171 s

We now define the *rotational energy* as

$$E_{\text{rot}} = \tfrac{1}{2}\Theta\,\omega^2 = \frac{L^2}{2\Theta}\,. \tag{23}$$

The expression is similar to the expression for the kinetic energy of a particle. Can you guess how much larger the rotational energy of the Earth is compared with the yearly

* Extrinsic and intrinsic moment of inertia are related by

$$\Theta_{\text{ext}} = \Theta_{\text{int}} + md^2\,, \tag{22}$$

where d is the distance between the centre of mass and the axis of extrinsic rotation. This relation is called *Steiner's parallel axis theorem*. Are you able to deduce it?

Challenge 170 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

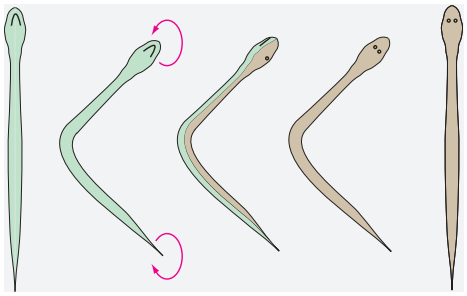

FIGURE 62 How a snake turns itself around its axis

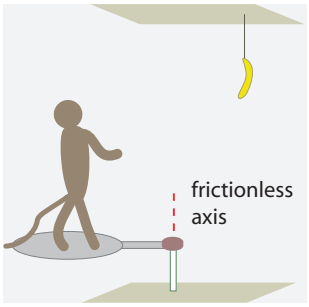

FIGURE 63 Can the ape reach the banana?

Challenge 172 s electricity usage of humanity? In fact, if you could find a way to harness this energy, you would become famous. For undistorted rotated objects, rotational energy is conserved.

Every object that has an orientation also has an intrinsic angular momentum. (What Challenge 173 s about a sphere?) Therefore, point particles do not have intrinsic angular momenta – at least in first approximation. (This conclusion will change in quantum theory.) The *extrinsic* angular momentum $\boldsymbol{L}$ of a point particle is given by

$$\boldsymbol{L} = \boldsymbol{r} \times \boldsymbol{p} = \frac{2\boldsymbol{a}(T)m}{T} \quad \text{so that} \quad L = r\,p = \frac{2A(T)m}{T} \tag{24}$$

where $\boldsymbol{p}$ is the momentum of the particle, $\boldsymbol{a}(T)$ is the surface swept by the position vector $\boldsymbol{r}$ of the particle during time T.* The angular momentum thus points along the rotation axis, following the right-hand rule, as shown in Figure 61.

As in the case of linear motion, rotational energy and angular momentum are not always conserved in the macroscopic world: rotational energy can change due to friction, and angular momentum can change due to external forces (torques). However, for closed (undisturbed) systems both quantities are always conserved. In particular, on a microscopic scale, most objects are undisturbed, so that conservation of rotational energy and angular momentum is especially obvious there.

---

* For the curious, the result of the *cross product* or *vector product* $\boldsymbol{a} \times \boldsymbol{b}$ between two vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ is defined as that vector that is orthogonal to both, whose orientation is given by the *right-hand rule*, and whose length is given by $ab \sin \sphericalangle(\boldsymbol{a}, \boldsymbol{b})$, i.e., by the surface area of the parallelogram spanned by the two Challenge 174 e vectors. From the definition you can show that the vector product has the properties

$$\begin{aligned}
&\boldsymbol{a} \times \boldsymbol{b} = -\boldsymbol{b} \times \boldsymbol{a}\,, \quad \boldsymbol{a} \times (\boldsymbol{b} + \boldsymbol{c}) = \boldsymbol{a} \times \boldsymbol{b} + \boldsymbol{a} \times \boldsymbol{c}\,, \quad \lambda \boldsymbol{a} \times \boldsymbol{b} = \lambda(\boldsymbol{a} \times \boldsymbol{b}) = \boldsymbol{a} \times \lambda \boldsymbol{b}\,, \quad \boldsymbol{a} \times \boldsymbol{a} = \boldsymbol{0}\,, \\
&\boldsymbol{a}(\boldsymbol{b} \times \boldsymbol{c}) = \boldsymbol{b}(\boldsymbol{c} \times \boldsymbol{a}) = \boldsymbol{c}(\boldsymbol{a} \times \boldsymbol{b})\,, \quad \boldsymbol{a} \times (\boldsymbol{b} \times \boldsymbol{c}) = \boldsymbol{b}(\boldsymbol{ac}) - \boldsymbol{c}(\boldsymbol{ab})\,, \\
&(\boldsymbol{a} \times \boldsymbol{b})(\boldsymbol{c} \times \boldsymbol{d}) = \boldsymbol{a}(\boldsymbol{b} \times (\boldsymbol{c} \times \boldsymbol{d})) = (\boldsymbol{ac})(\boldsymbol{bd}) - (\boldsymbol{bc})(\boldsymbol{ad})\,, \\
&(\boldsymbol{a} \times \boldsymbol{b}) \times (\boldsymbol{c} \times \boldsymbol{d}) = \boldsymbol{c}((\boldsymbol{a} \times \boldsymbol{b})\boldsymbol{d}) - \boldsymbol{d}((\boldsymbol{a} \times \boldsymbol{b})\boldsymbol{c})\,, \quad \boldsymbol{a} \times (\boldsymbol{b} \times \boldsymbol{c}) + \boldsymbol{b} \times (\boldsymbol{c} \times \boldsymbol{a}) + \boldsymbol{c} \times (\boldsymbol{a} \times \boldsymbol{b}) = 0\,.
\end{aligned} \tag{25}$$

Page 885 The vector product exists (almost) only in three-dimensional vector spaces. (See Appendix B.) The cross product vanishes if and only if the vectors are parallel. The parallelepiped spanned by three vectors $\boldsymbol{a}$, $\boldsymbol{b}$ and Challenge 175 e $\boldsymbol{c}$ has the volume $V = \boldsymbol{c}\,(\boldsymbol{a} \times \boldsymbol{b})$. The pyramid or tetrahedron formed by the three vectors has one sixth of that volume.

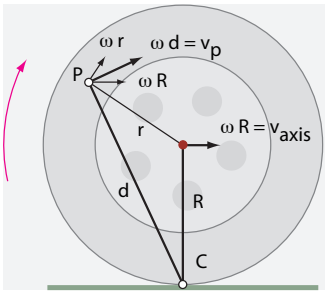

FIGURE 64 The velocities and unit vectors for a rolling wheel

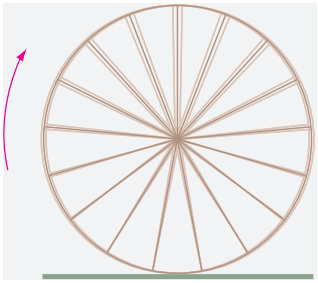

FIGURE 65 A simulated photograph of a rolling wheel with spokes

On a frictionless surface, as approximated by smooth ice or by a marble floor covered by a layer of oil, it is impossible to move forward. In order to move, we need to push *against* something. Is this also the case for rotation?

We note that the effects of rotation and many sensors for rotation are the same as for acceleration. But a few sensors for rotation are fundamentally new. In particular, we will Page 120 meet the gyroscope shortly.

Surprisingly, it is possible to turn even *without* pushing against something. You can check this on a well-oiled rotating office chair: simply rotate an arm above the head. After each turn of the hand, the orientation of the chair has changed by a small amount. Indeed, conservation of angular momentum and of rotational energy do not prevent bodies from changing their orientation. Cats learn this in their youth. After they have learned the trick, if they are dropped legs up, they can turn themselves in such a way that they always Ref. 74 land feet first. Snakes also know how to rotate themselves, as Figure 62 shows. During the Olympic Games one can watch board divers and gymnasts perform similar tricks. Challenge 176 d Rotation is thus different from translation in this aspect. (Why?)

Angular momentum is conserved. This statement is valid for any axis, provided that external forces (torques) play no role. To make the point, Jean-Marc Lévy-Leblond poses Ref. 2 the problem of Figure 63. Can the ape reach the banana without leaving the plate, assuming Challenge 177 s that the plate on which the ape rests can turn around the axis without friction?

Rolling wheels

Rotation is an interesting phenomenon in many ways. A rolling wheel does *not* turn around its axis, but around its point of contact. Let us show this.

A wheel of radius R is *rolling* if the speed of the axis v_{axis} is related to the angular velocity ω by

$$\omega = \frac{v_{\text{axis}}}{R} \,. \tag{26}$$

For any point P on the wheel, with distance r from the axis, the velocity v_{P} is the sum of the motion of the axis and the motion around the axis. Figure 64 shows that v_{P} is orthogonal to d, the distance between the point P and the contact point of the wheel. Challenge 178 e The figure also shows that the length ratio between v_{P} and d is the same as between v_{axis}

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

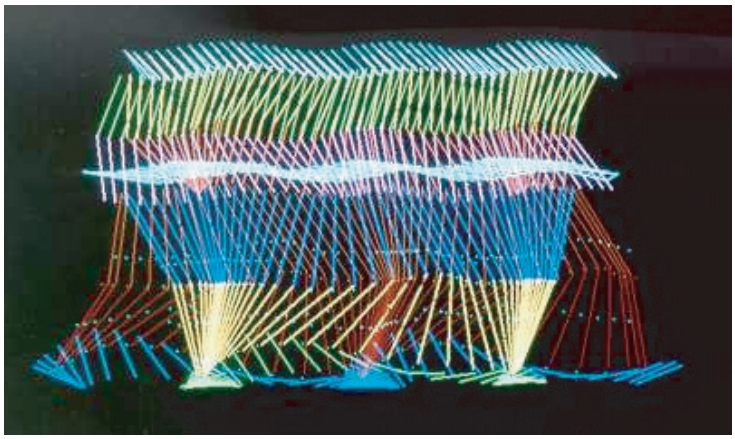

FIGURE 66 The measured motion of a walking human (© Ray McCoy)

and R. As a result, we can write

$$\boldsymbol{v}_P = \boldsymbol{\omega} \times \boldsymbol{d} \,, \tag{27}$$

which shows that a rolling wheel does indeed rotate about its point of contact with the ground.

Surprisingly, when a wheel rolls, some points on it move towards the wheel's axis, some stay at a fixed distance and others move away from it. Can you determine where these various points are located? Together, they lead to an interesting pattern when a rolling wheel with spokes, such as a bicycle wheel, is photographed.

Challenge 179 s
Ref. 75
Ref. 76

With these results you can tackle the following beautiful challenge. When a turning bicycle wheel is put on a slippery surface, it will slip for a while and then end up rolling. How does the final speed depend on the initial speed and on the friction?

Challenge 180 d

How do we walk?

> Golf is a good walk spoiled.
>
> Mark Twain

Why do we move our arms when walking or running? To save energy or to be graceful? In fact, whenever a body movement is performed with as little energy as possible, it is natural and graceful. This correspondence can indeed be taken as the actual definition of grace. The connection is common knowledge in the world of dance; it is also a central aspect of the methods used by actors to learn how to move their bodies as beautifully as possible.

Ref. 20

To convince yourself about the energy savings, try walking or running with your arms fixed or moving in the opposite direction to usual: the effort required is considerably higher. In fact, when a leg is moved, it produces a torque around the body axis which has to be counterbalanced. The method using the least energy is the swinging of arms. Since the arms are lighter than the legs, they must move further from the axis of the body, to compensate for the momentum; evolution has therefore moved the attachment of the arms, the shoulders, farther apart than those of the legs, the hips. Animals on two

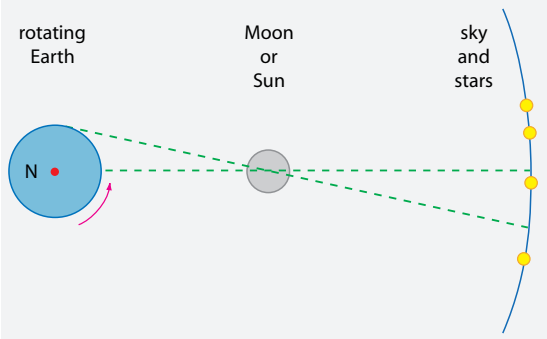

FIGURE 67 The parallax – not drawn to scale

legs but no arms, such as penguins or pigeons, have more difficulty walking; they have to move their whole torso with every step.

Which muscles do most of the work when walking, the motion that experts call *gait*? Ref. 77 In 1980, Serge Gracovetsky found that in human gait a large fraction of the power comes from the muscles along the *spine*, not from those of the legs. (Indeed, people without legs are also able to walk. However, a number of muscles in the legs must work in oder to walk normally.) When you take a step, the lumbar muscles straighten the spine; this automatically makes it turn a bit to one side, so that the knee of the leg on that side automatically comes forward. When the foot is moved, the lumbar muscles can relax, and then straighten again for the next step. In fact, one can experience the increase in Challenge 181 e tension in the *back* muscles when walking without moving the arms, thus confirming where the human engine is located.

Human legs differ from those of apes in a fundamental aspect: humans are able to run. In fact the whole human body has been optimized for running, an ability that no other primate has. The human body has shed most of its hair to achieve better cooling, has evolved the ability to run while keeping the head stable, has evolved the right length of arms for proper balance when running, and even has a special ligament in the back that works as a shock absorber while running. In other words, running is the most human of all forms of motion.

The Earth's crust is less dense (2.7 kg/l) than the Earth's mantle (3.1 kg/l) and floats on it. As a result, the lighter crust below a mountain ridge must be much deeper than below a plain. If a mountain rises 1 km above the plain, how much deeper must the crust be below it? The simple block model shown in Figure 69 works fairly well; first, it explains why, near mountains, measurements of the deviation of free fall from the vertical line lead to so much lower values than those expected without a deep crust. Later, sound measurements have confirmed directly that the continental crust is indeed thicker beneath mountains. Challenge 186 s

FIGURE 70 A well-known toy

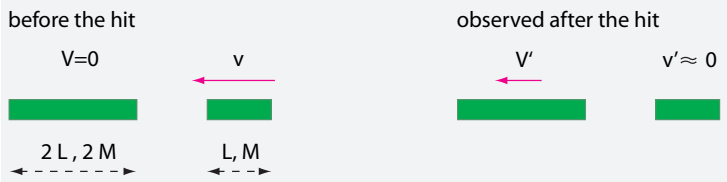

FIGURE 71 An elastic collision that seems not to obey energy conservation

* *

In early 2004, two men and a woman earned £ 1.2 million in a single evening in a London casino. They did so by applying the formulae of Galilean mechanics. They used the method pioneered by various physicists in the 1950s who built various small computers that could predict the outcome of a roulette ball from the initial velocity imparted by the croupier. In the case in Britain, the group added a laser scanner to a smart phone that measured the path of a roulette ball and predicted the numbers where it would arrive. In this way, they increased the odds from 1 in 37 to about 1 in 6. After six months of investigations, Scotland Yard ruled that they could keep the money they won.

Ref. 79

In fact around the same time, a few people earned around 400 000 euro over a few weeks by using the same method in Germany, but with no computer at all. In certain casinos, machines were throwing the roulette ball. By measuring the position of the zero to the incoming ball with the naked eye, these gamblers were able to increase the odds of the bets they placed during the last allowed seconds and thus win a considerable sum purely through fast reactions.

* *

The toy of Figure 70 shows interesting behaviour: when a number of spheres are lifted and dropped to hit the resting ones, the same number of spheres detach on the other side, whereas the previously dropped spheres remain motionless. At first sight, all this seems to follow from energy and momentum conservation. However, energy and momentum conservation provide only two equations, which are insufficient to explain or determine the behaviour of five spheres. Why then do the spheres behave in this way? And why do they all swing in phase when a longer time has passed?

Challenge 188 d

* *

A surprising effect is used in home tools such as hammer drills. We remember that when a small ball elastically hits a large one at rest, both balls move after the hit, and the small one obviously moves faster than the large one. Despite this result, when a short cylin-

Summary on conservation

> The gods are not as rich as one might think: what they give to one, they take away from the other.
>
> Antiquity

We have encountered four conservation principles that are valid for closed systems in everyday life:

— conservation of total linear momentum,
— conservation of total angular momentum,
— conservation of total energy,
— conservation of total mass.

Later on, the theory of special relativity will show that the last two quantities are conserved only when taken together. None of these conservation laws applies to motion of images.

These conservation principles are among the great results in science. They limit the surprises that nature can offer: conservation means that linear momentum, angular momentum, and mass–energy can neither be created from nothing, nor can they disappear into nothing. Conservation limits creation. The above quote, almost blasphemous, expresses this idea.

Page 219

Later on we will find out that these results could have been deduced from three simple observations: closed systems behave the same independently of where they are, in what direction they are oriented and of the time at which they are set up. Motion is universal. In more abstract and somewhat more general terms, physicists like to say that all conservation principles are consequences of the invariances, or symmetries, of nature.

Chapter 5

FROM THE ROTATION OF THE EARTH TO THE RELATIVITY OF MOTION

> Eppur si muove!
>
> Anonymous*

Is the Earth rotating? The search for answers to this question gives a beautiful cross section of the history of classical physics. Around the year 265 BCE, the Greek thinker Ref. 82 Aristarchos of Samos maintained that the Earth rotates. He had measured the parallax of the Moon (today known to be up to 0.95°) and of the Sun (today known to be 8.8′).** The *parallax* is an interesting effect; it is the angle describing the difference between the directions of a body in the sky when seen by an observer on the surface of the Earth and when seen by a hypothetical observer at the Earth's centre. (See Figure 67.) Aristarchos noticed that the Moon and the Sun *wobble* across the sky, and this wobble has a period of 24 hours. He concluded that the Earth rotates.

Page 403 Measurements of the aberration of light also show the rotation of the Earth; it can be detected with a telescope while looking at the stars. The *aberration* is a change of the expected light direction, which we will discuss shortly. At the Equator, Earth rotation adds an angular deviation of 0.32′, changing sign every 12 hours, to the aberration due to the motion of the Earth around the Sun, about 20.5′. In modern times, astronomers have found a number of additional proofs, but none is accessible to the man on the street.

Furthermore, the measurements showing that the Earth is not a sphere, but is *flattened* at the poles, confirmed the rotation of the Earth. Again, however, this eighteenth century measurement by Maupertuis*** is not accessible to everyday observation.

Then, in the years 1790 to 1792 in Bologna, Giovanni Battista Guglielmini (1763–1817) finally succeeded in measuring what Galileo and Newton had predicted to be the simplest proof for the Earth's rotation. On the Earth, objects do not fall vertically, but are slightly deviated to the east. This deviation appears because an object keeps the larger hor-

* 'And yet she moves' is the sentence about the Earth attributed, most probably incorrectly, to Galileo since the 1640s. It is true, however, that at his trial he was forced to publicly retract the statement of a moving Earth to save his life. For more details, see the section on page 252.

** For the definition of angles see page 68, and for the definition of angle units see Appendix C.

*** Pierre Louis Moreau de Maupertuis (1698–1759), French physicist and mathematician. He was one of the key figures in the quest for the principle of least action, which he named in this way. He was also founding president of the Berlin Academy of Sciences. Maupertuis thought that the principle reflected the maximization of goodness in the universe. This idea was thoroughly ridiculed by Voltaire in this *Histoire du Docteur Akakia et du natif de Saint-Malo*, 1753. Maupertuis (www.voltaire-integral.com/Html/23/08DIAL.htm) performed his measurement of the Earth to distinguish between the theory of gravitation of Newton and that of Descartes, who had predicted that the Earth is elongated at the poles, instead of flattened.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

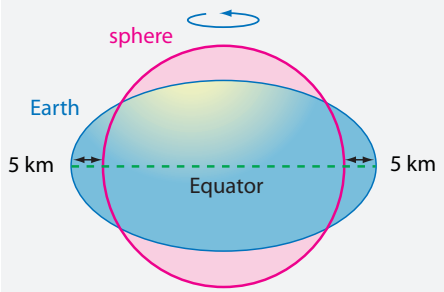

FIGURE 76 Earth's deviation from spherical shape due to its rotation (exaggerated)

FIGURE 77 The Coriolis effect: on a rotating object, freely moving object deviate from the straight line

izontal velocity it had at the height from which it started falling, as shown in Figure 78. Guglielmini's result was the first non-astronomical proof of the Earth's rotation. The experiments were repeated in 1802 by Johann Friedrich Benzenberg (1777–1846). Using metal balls which he dropped from the Michaelis tower in Hamburg – a height of 76 m – Benzenberg found that the deviation to the east was 9.6 mm. Can you confirm that the value measured by Benzenberg almost agrees with the assumption that the Earth turns once every 24 hours? (There is also a much smaller deviation towards the Equator, not measured by Guglielmini, Benzenberg or anybody after them up to this day; however, it completes the list of effects on free fall by the rotation of the Earth.) Both deviations are easily understood if we use the result (described below) that falling objects describe an ellipse around the centre of the rotating Earth. The elliptical shape shows that the path of a thrown stone does not lie on a plane for an observer standing on Earth; for such an observer, the exact path thus cannot be drawn on a piece of paper.

Challenge 206 ny

Page 155

In 1835, Gustave-Gaspard Coriolis discovered a closely related effect that nobody had as yet noticed in everyday life. Imagine a ball that rolls over a table. For a person on the floor, the ball rolls in a straight line. Now imagine that the table rotates. For the person on the floor, the ball still rolls in a straight line. But for a person on the rotating table, the ball traces a *curved* path. In short, any object that travels in a rotating background is subject to a transversal acceleration. This is the so-called *Coriolis acceleration* (or Coriolis effect).

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

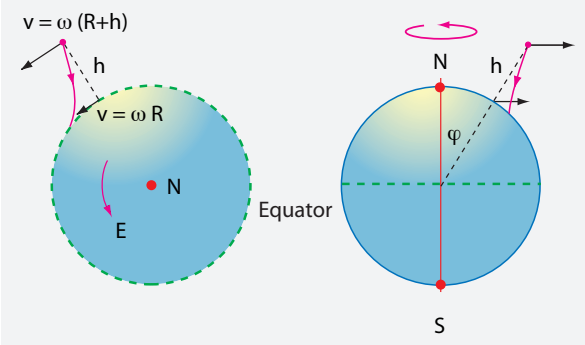

FIGURE 78 The deviations of free fall towards the east and towards the Equator due to the rotation of the Earth

Now, the Earth is a rotating background. On the northern hemisphere, the rotation is anticlockwise. As the result, any moving object is slightly deviated to the right (while the magnitude of its velocity stays constant). On Earth, like on all rotating backgrounds, the *Coriolis acceleration* $\boldsymbol{a}$ results from the change of distance to the rotation axis. Can you deduce the analytical expression for it, namely $\boldsymbol{a}_C = -2\boldsymbol{\omega} \times \boldsymbol{v}$?

Challenge 207 s

On Earth, the Coriolis acceleration generally has a small value. Therefore it is best observed either in large-scale or high-speed phenomena. Indeed, the Coriolis acceleration determines the handedness of many large-scale phenomena with a spiral shape, such as the directions of cyclones and anticyclones in meteorology, the general wind patterns on Earth and the deflection of ocean currents and tides. These phenomena have opposite handedness on the northern and the southern hemisphere. Most beautifully, the Coriolis acceleration explains why icebergs do not follow the direction of the wind as they drift away from the polar caps. The Coriolis acceleration also plays a role in the flight of cannon balls (that was the original interest of Coriolis), in satellite launches, in the motion of sunspots and even in the motion of electrons in molecules. All these phenomena are of opposite sign on the northern and southern hemispheres and thus prove the rotation of the Earth. (In the First World War, many naval guns missed their targets in the southern hemisphere because the engineers had compensated them for the Coriolis effect in the northern hemisphere.)

Ref. 83

Ref. 84

Only in 1962, after several earlier attempts by other researchers, Asher Shapiro was the first to verify that the Coriolis effect has a tiny influence on the direction of the vortex formed by the water flowing out of a bathtub. Instead of a normal bathtub, he had to use a carefully designed experimental set-up because, contrary to an often-heard assertion, no such effect can be seen in a real bathtub. He succeeded only by carefully eliminating all disturbances from the system; for example, he waited 24 hours after the filling of the reservoir (and never actually stepped in or out of it!) in order to avoid any left-over motion of water that would disturb the effect, and built a carefully designed, completely rotationally-symmetric opening mechanism. Others have repeated the experiment in the southern hemisphere, finding opposite rotation direction and thus confirming the result. In other words, the handedness of usual bathtub vortices is *not* caused by the rotation of the Earth, but results from the way the water starts to flow out. But let us go on with the story about the Earth's rotation.

Ref. 85

Ref. 85

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

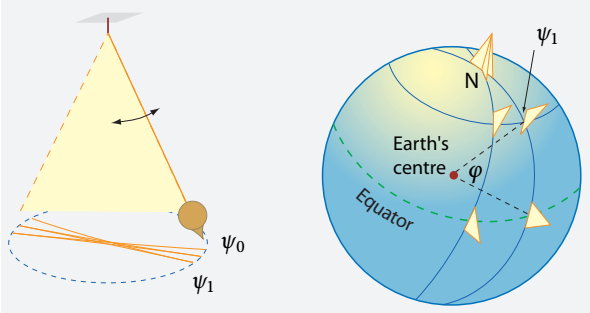

FIGURE 79 The turning motion of a pendulum showing the rotation of the Earth

In 1851, the French physician-turned-physicist Jean Bernard Léon Foucault (b. 1819 Paris, d. 1868 Paris) performed an experiment that removed all doubts and rendered him world-famous practically overnight. He suspended a 67 m long pendulum* in the Panthéon in Paris and showed the astonished public that the direction of its swing changed over time, rotating slowly. To anybody with a few minutes of patience to watch the change of direction, the experiment proved that the Earth rotates. If the Earth did not rotate, the swing of the pendulum would always continue in the same direction. On a rotating Earth, in Paris, the direction changes to the right, in clockwise sense, as shown in Figure 79. The direction does not change if the pendulum is located at the Equator, and it changes to the left in the southern hemisphere.** A modern version of the pendulum can be observed via the web cam at pendelcam.kip.uni-heidelberg.de/; high speed films of the pendulum's motion during day and night can be downloaded at www.kip.uni-heidelberg.de/OeffWiss/Pendel-Internetauftritt/zeitraffer.php. (Several pendulum animations, with exaggerated deviation, can be found at commons.wikimedia.org/wiki/Foucault_pendulum).

The time over which the orientation of the pendulum's swing performs a full turn – the *precession time* – can be calculated. Study a pendulum starting to swing in the North–South direction and you will find that the precession time T_{Foucault} is given by

Challenge 209 d

$$T_{\text{Foucault}} = \frac{23\,\text{h}\ 56\,\text{min}}{\sin\varphi} \tag{28}$$

where φ is the latitude of the location of the pendulum, e.g. 0° at the Equator and 90° at the North Pole. This formula is one of the most beautiful results of Galilean kinematics.***

Challenge 208 d
Ref. 86

* Why was such a long pendulum necessary? Understanding the reasons allows one to repeat the experiment at home, using a pendulum as short as 70 cm, with the help of a few tricks. To observe the effect with a simple set-up, attach a pendulum to your office chair and rotate the chair slowly.

** The discovery also shows how precision and genius go together. In fact, the first person to observe the effect was Vincenzo Viviani, a student of Galilei, as early as 1661! Indeed, Foucault had read about Viviani's work in the publications of the Academia dei Lincei. But it took Foucault's genius to connect the effect to the rotation of the Earth; nobody had done so before him.

*** The calculation of the period of Foucault's pendulum assumes that the precession rate is constant during a rotation. This is only an approximation (though usually a good one).

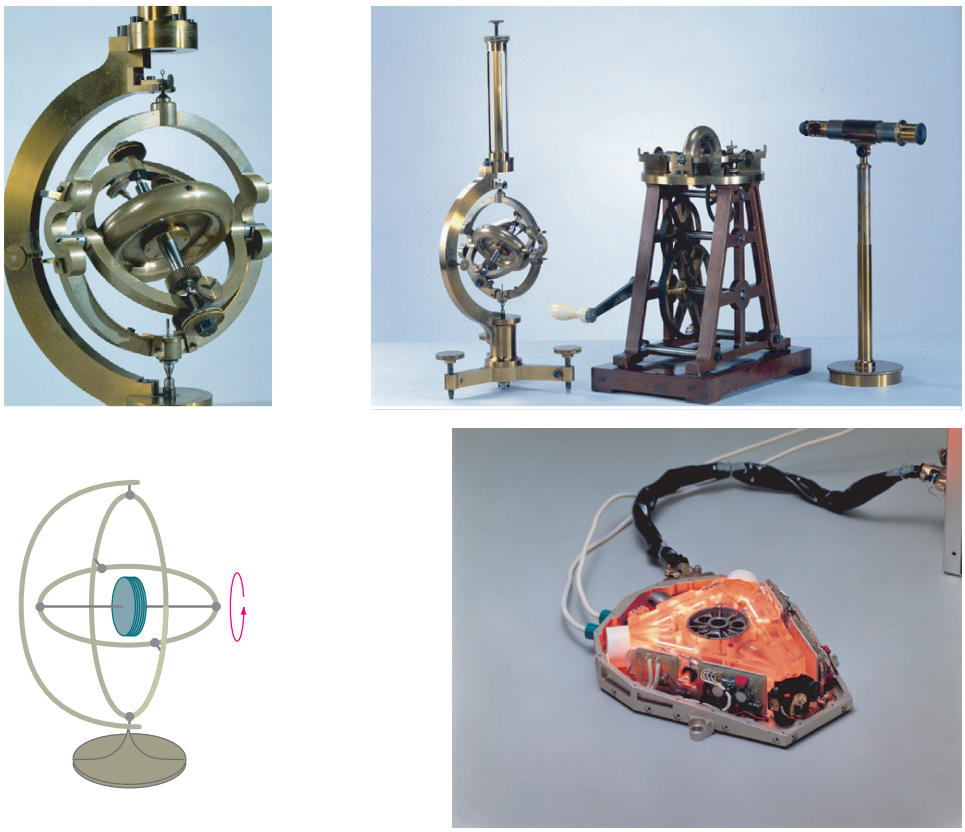

FIGURE 80 The gyroscope: the original system by Foucault with its freely movable spinning top, the mechanical device to bring it to speed, the optical device to detect its motion, the general construction principle, and a modern (triangular) ring laser gyroscope, based on colour change of rotating laser light instead of angular changes of a rotating mass (© CNAM, JAXA)

Foucault was also the inventor and namer of the *gyroscope*. He built the device, shown in Figure 80, in 1852, one year after his pendulum. With it, he again demonstrated the rotation of the Earth. Once a gyroscope rotates, the axis stays fixed in space – but only when seen from distant stars or galaxies. (This is not the same as talking about absolute space. Why?) For an observer on Earth, the axis direction changes regularly with a period of 24 hours. Gyroscopes are now routinely used in ships and in aeroplanes to give the direction of north, because they are more precise and more reliable than magnetic compasses. In the most modern versions, one uses laser light running in circles instead of rotating masses.*

Challenge 210 s

In 1909, Roland von Eötvös measured a simple effect: due to the rotation of the Earth, the weight of an object depends on the direction in which it moves. As a result, a balance in rotation around the vertical axis does not stay perfectly horizontal: the balance starts to oscillate slightly. Can you explain the origin of the effect?

Challenge 212 s

Challenge 211 s * Can you guess how rotation is detected in this case?

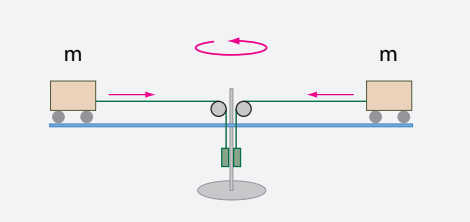

FIGURE 81 Showing the rotation of the Earth through the rotation of an axis

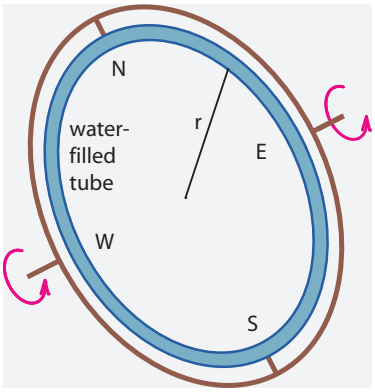

FIGURE 82 Demonstrating the rotation of the Earth with water

Ref. 87 In 1910, John Hagen published the results of an even simpler experiment, proposed by Louis Poinsot in 1851. Two masses are put on a horizontal bar that can turn around a vertical axis, a so-called *isotomeograph*. If the two masses are slowly moved towards the support, as shown in Figure 81, and if the friction is kept low enough, the bar rotates. Obviously, this would not happen if the Earth were not rotating. Can you explain the Challenge 213 s observation? This little-known effect is also useful for winning bets between physicists.

Ref. 88 In 1913, Arthur Compton showed that a closed tube filled with water and some small floating particles (or bubbles) can be used to show the rotation of the Earth. The device is called a *Compton tube* or *Compton wheel*. Compton showed that when a horizontal tube filled with water is rotated by 180°, something happens that allows one to prove that the Earth rotates. The experiment, shown in Figure 82, even allows measurement of the Challenge 214 d latitude of the point where the experiment is made. Can you guess what happens?

Page 1006 In 1925, Albert Michelson* and his collaborators in Illinois built several interferometers for light and detected the rotation of the Earth. One system is shown in Figure 83; the largest interferometer they constructed had an arm length of 32 m. Interferometers produce bright and dark fringes of light; the position of the fringes depends on the speed at which the interferometers rotates. The fringe shift is due to an effect first measured in 1913 by the French physicist Georges Sagnac: the rotation of a complete ring interferometer with angular frequency (vector) $\boldsymbol{\Omega}$ produces a fringe shift of angular phase $\Delta\varphi$ given Challenge 215 s by

$$\Delta\varphi = \frac{8\pi\, \boldsymbol{\Omega}\, \boldsymbol{a}}{c\,\lambda} \tag{29}$$

where $\boldsymbol{a}$ is the area (vector) enclosed by the two interfering light rays, λ their wavelength and c the speed of light. The effect is now called the *Sagnac effect*, even though it had Ref. 89 already been predicted 20 years earlier by Oliver Lodge.** Also for a fixed interferometer, Michelson and his team found a fringe shift with a period of 24 hours and of exactly

* Albert Abraham Michelson (b. 1852 Strelno, d. 1931 Pasadena) Prussian–Polish–US-American physicist, obsessed by the precise measurement of the speed of light, received the Nobel Prize in Physics in 1907.

** Oliver Lodge (1851–1940) was a British physicist who studied electromagnetic waves and tried to commu-

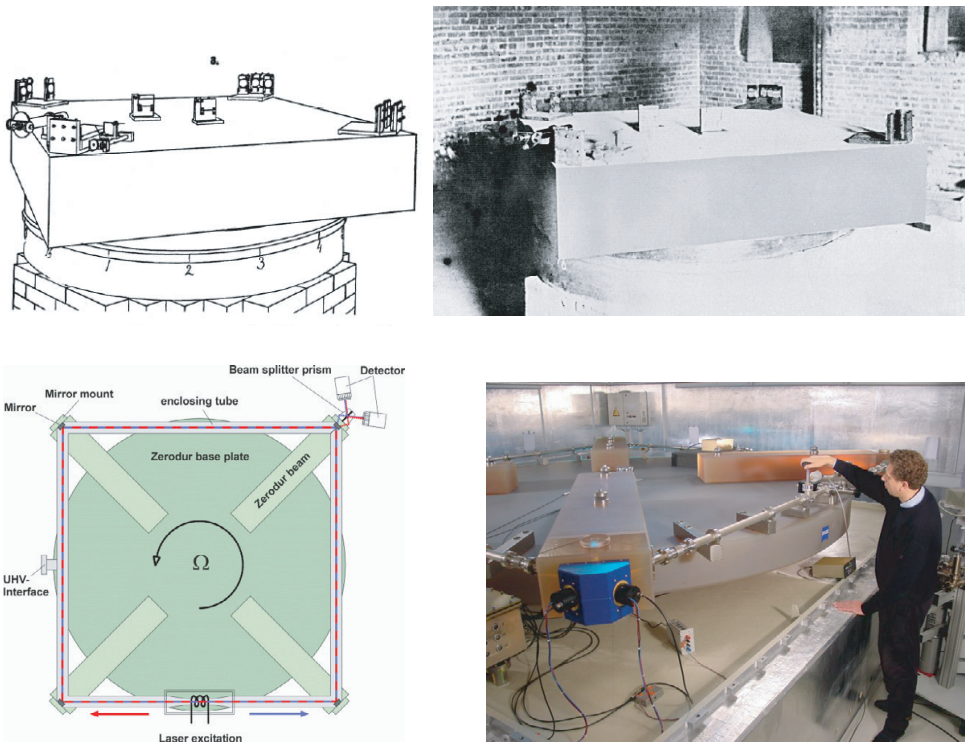

FIGURE 83 One of the early interferometers built by Michelson and Morley, and a modern precision ring laser interferometer (© Bundesamt für Kartographie und Geodäsie, Carl Zeiss)

the magnitude predicted by the rotation of the Earth with equation (29). Modern high precision versions use ring lasers with areas of only a few square metres, but which are able to measure variations of the rotation rates of the Earth of less than one part per million. Indeed, over the course of a year the length of a day varies irregularly by a few milliseconds, mostly due to influences from the Sun or the Moon, due to weather changes and due to hot magma flows deep inside the Earth.* But also earthquakes, the El Niño effect in the climate and the filling of large water dams have effects on the rotation of the Earth. All these effects can be studied with such precision interferometers; these can also be used for research into the motion of the soil due to lunar tides or earthquakes, and for checks on the theory of special relativity.

Ref. 90

In 1948, Hans Bucka developed the simplest experiment so far to show the rotation of the Earth. A metal rod allows one to detect the rotation of the Earth after only a few seconds of observation. The experiment can be easily be performed in class. Can you guess how it works?

Ref. 91

Challenge 216 s

nicate with the dead. A strange but influential figure, his ideas are often cited when fun needs to be made of physicists; for example, he was one of those (rare) physicists who believed that at the end of the nineteenth century physics was complete.

* The growth of leaves on trees and the consequent change in the Earth's moment of inertia, already studied in 1916 by Harold Jeffreys, is way too small to be seen, so far.

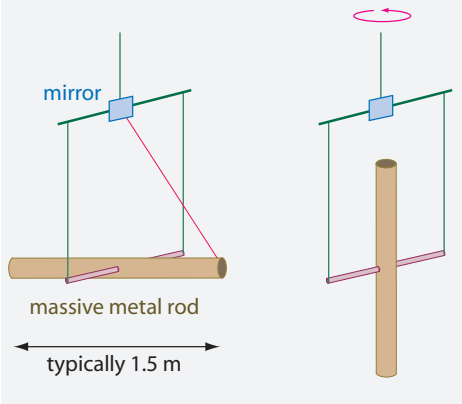

FIGURE 84 Observing the rotation of the Earth in two seconds

In summary, observations show that the Earth surface rotates at 463 m/s at the Equator, a larger value than that of the speed of sound in air – about 340 m/s in usual conditions – and that we are in fact *whirling* through the universe.

How does the Earth rotate?

Is the rotation of the Earth *constant* over geological time scales? That is a hard question. If you find a method leading to an answer, publish it! (The same is true for the question whether the length of the year is constant.) Only a few methods are known, as we will find out shortly.

Ref. 92

The rotation of the Earth is not even constant during a human lifespan. It varies by a few parts in 10^8. In particular, on a 'secular' time scale, the length of the day increases by about 1 to 2 ms per century, mainly because of the friction by the Moon and the melting of the polar ice caps. This was deduced by studying historical astronomical observations of the ancient Babylonian and Arab astronomers. Additional 'decadic' changes have an amplitude of 4 or 5 ms and are due to the motion of the liquid part of the Earth's core.

Ref. 93

The seasonal and biannual changes of the length of the day – with an amplitude of 0.4 ms over six months, another 0.5 ms over the year, and 0.08 ms over 24 to 26 months – are mainly due to the effects of the atmosphere. In the 1950s the availability of precision measurements showed that there is even a 14 and 28 day period with an amplitude of 0.2 ms, due to the Moon. In the 1970s, when wind oscillations with a length scale of about 50 days were discovered, they were also found to alter the length of the day, with an amplitude of about 0.25 ms. However, these last variations are quite irregular.

But why does the Earth rotate at all? The rotation derives from the rotating gas cloud at the origin of the solar system. This connection explains that the Sun and all planets, except one, turn around themselves in the same direction, and that they also all turn around the Sun in that same direction. But the complete story is outside the scope of this text.

Ref. 94

The rotation around its axis is not the only motion of the Earth; it performs other motions as well. This was already known long ago. In 128 BCE, the Greek astronomer Hipparchos discovered what is today called the *(equinoctial) precession*. He compared a

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

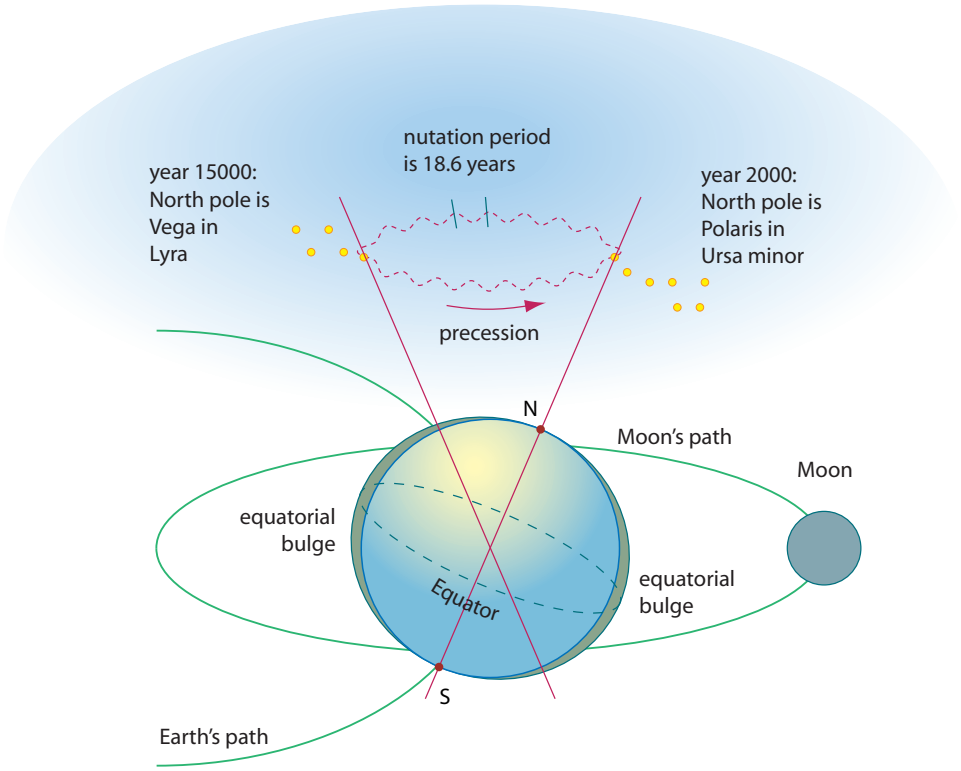

FIGURE 85 The precession and the nutation of the Earth's axis

measurement he made himself with another made 169 years before. Hipparchos found that the Earth's axis points to different stars at different times. He concluded that the sky was moving. Today we prefer to say that the axis of the Earth is moving. During a period of 25 800 years the axis draws a cone with an opening angle of 23.5°. This motion, shown in Figure 85, is generated by the tidal forces of the Moon and the Sun on the equatorial bulge of the Earth that results form its flattening. The Sun and the Moon try to align the axis of the Earth at right angles to the Earth's path; this torque leads to the precession of the Earth's axis.

Precession is a motion common to all rotating systems: it appears in planets, spinning tops and atoms. (Precession is also at the basis of the surprise related to the suspended wheel shown on page 191.) Precession is most easily seen in spinning tops, be they suspended or not. An example is shown in Figure 86; for atomic nuclei or planets, just imagine that the suspending wire is missing and the rotating body less flat.

In addition, the axis of the Earth is not even fixed relative to the Earth's surface. In 1884, by measuring the exact angle above the horizon of the celestial North Pole, Friedrich Küstner (1856–1936) found that the axis of the Earth *moves* with respect to the Earth's crust, as Bessel had suggested 40 years earlier. As a consequence of Küstner's discovery, the International Latitude Service was created. The *polar motion* Küstner discovered turned out to consist of three components: a small linear drift – not yet understood – a

yearly elliptical motion due to seasonal changes of the air and water masses, and a circular motion* with a period of about 1.2 years due to fluctuations in the pressure at the bottom of the oceans. In practice, the North Pole moves with an amplitude of about 15 m around an average central position, as shown in Figure 87. Short term variations of the

Ref. 95

* The circular motion, a wobble, was predicted by the great Swiss mathematician Leonhard Euler (1707–1783). In an incredible story, using Euler's and Bessel's predictions and Küstner's data, in 1891 Seth Chandler claimed to be the discoverer of the circular component.

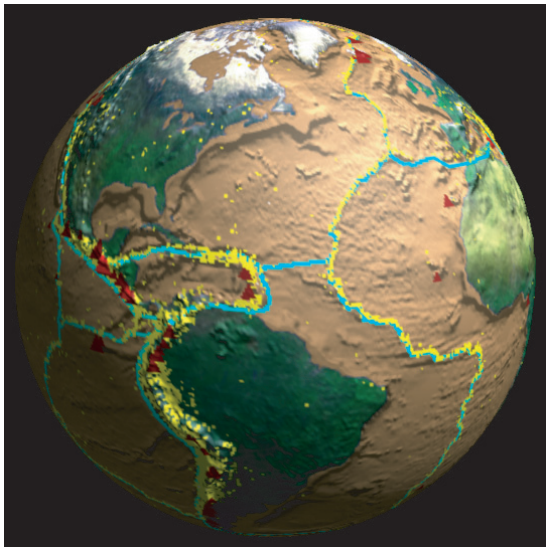

FIGURE 88 The continental plates are the objects of tectonic motion

North Pole position, due to local variations in atmospheric pressure, to weather change and to the tides, have also been measured. Ref. 96

In 1912, the German meteorologist and geophysicist Alfred Wegener (1880–1930) discovered an even larger effect. After studying the shapes of the continental shelves and the geological layers on both sides of the Atlantic, he conjectured that the continents *move*, and that they are all fragments of a single continent that broke up 200 million years ago.*

Even though at first derided across the world, Wegener's discoveries were correct. Modern satellite measurements, shown in Figure 88, confirm this model. For example, the American continent moves away from the European continent by about 10 mm every year. There are also speculations that this velocity may have been much higher at certain periods in the past. The way to check this is to look at the magnetization of sedimental rocks. At present, this is still a hot topic of research. Following the modern version of the model, called *plate tectonics*, the continents (with a density of $2.7 \cdot 10^3\,\mathrm{kg/m^3}$) float on the fluid mantle of the Earth (with a density of $3.1 \cdot 10^3\,\mathrm{kg/m^3}$) like pieces of cork on water, and the convection inside the mantle provides the driving mechanism for the motion. Page 110, page 780 Ref. 97

Does the Earth move?

The centre of the Earth is not at rest in the universe. In the third century BCE Aristarchos of Samos maintained that the Earth turns around the Sun. However, a fundamental difficulty of the heliocentric system is that the stars look the same all year long. How can this be, if the Earth travels around the Sun? The distance between the Earth and the Sun has been known since the seventeenth century, but it was only in 1837 that Friedrich Wilhelm

* In this old continent, called Gondwanaland, there was a huge river that flowed westwards from the Chad to Guayaquil in Ecuador. After the continent split up, this river still flowed to the west. When the Andes appeared, the water was blocked, and many millions of years later, it flowed back. Today, the river still flows eastwards and is called the Amazon River.

FIGURE 89 Friedrich Wilhelm Bessel (1784–1846)

Bessel* became the first to observe the *parallax* of a star. This was a result of extremely careful measurements and complex calculations: he discovered the *Bessel functions* in order to realize it. He was able to find a star, 61 Cygni, whose apparent position changed with the month of the year. Seen over the whole year, the star describes a small ellipse in the sky, with an opening of 0.588″ (this is the modern value). After carefully eliminating all other possible explanations, he deduced that the change of position was due to the motion of the Earth around the Sun, and from the size of the ellipse he determined the distance to the star to be 105 Pm, or 11.1 light years.

Challenge 217 s

Bessel had thus managed for the first time to measure the distance of a star. By doing so he also proved that the Earth is not fixed with respect to the stars in the sky and that the Earth indeed revolves around the Sun. The motion itself was not a surprise. It confirmed the result of the mentioned aberration of light, discovered in 1728 by James Bradley** and to be discussed shortly; the Earth moves around the Sun.

Page 403

With the improvement of telescopes, other motions of the Earth were discovered. In 1748, James Bradley announced that there is a small regular *change* of the precession, which he called *nutation*, with a period of 18.6 years and an angular amplitude of 19.2″. Nutation occurs because the plane of the Moon's orbit around the Earth is not exactly the same as the plane of the Earth's orbit around the Sun. Are you able to confirm that this situation produces nutation?

Challenge 218 ny

Astronomers also discovered that the 23.5° tilt – or *obliquity* – of the Earth's axis, the angle between its intrinsic and its orbital angular momentum, actually changes from 22.1° to 24.5° with a period of 41 000 years. This motion is due to the attraction of the Sun and the deviations of the Earth from a spherical shape. In 1941, during the Second World War, the Serbian astronomer Milutin Milankovitch (1879–1958) retreated into solitude and studied the consequences. In his studies he realized that this 41 000 year period of the obliquity, together with an average period of 22 000 years due to precession,*** gives rise

* Friedrich Wilhelm Bessel (1784–1846), Westphalian astronomer who left a successful business career to dedicate his life to the stars, and became the foremost astronomer of his time.

** James Bradley, (1693–1762), English astronomer. He was one of the first astronomers to understand the value of precise measurement, and thoroughly modernized Greenwich. He discovered the aberration of light, a discovery that showed that the Earth moves and also allowed him to measure the speed of light; he also discovered the nutation of the Earth.

*** In fact, the 25 800 year precession leads to three insolation periods, of 23 700, 22 400 and 19 000 years,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

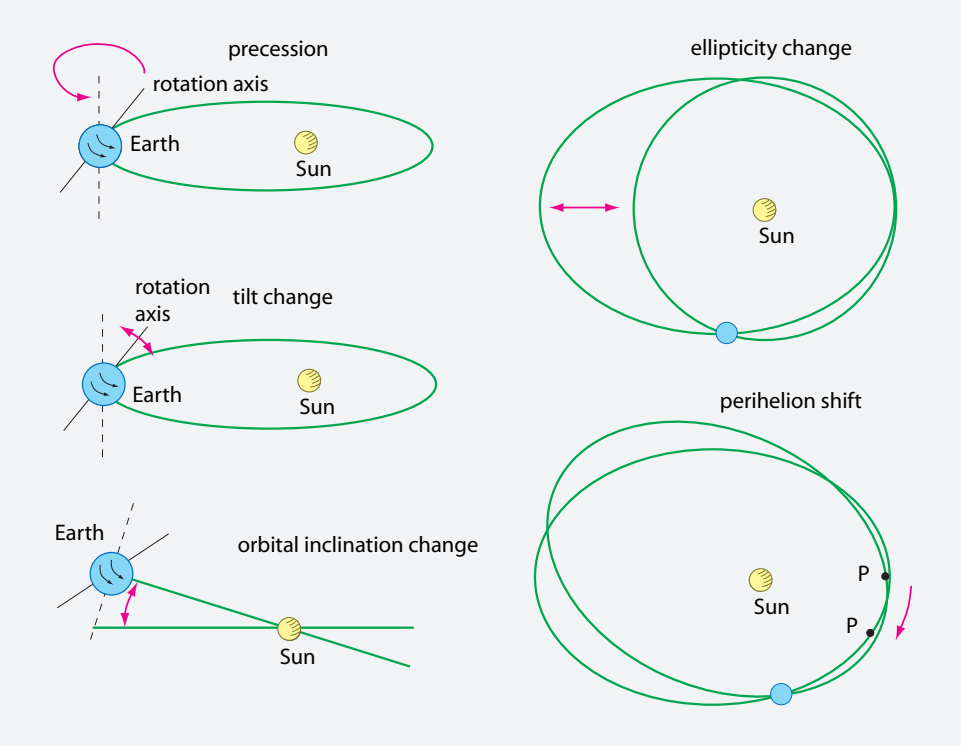

FIGURE 90 Changes in the Earth's motion around the Sun

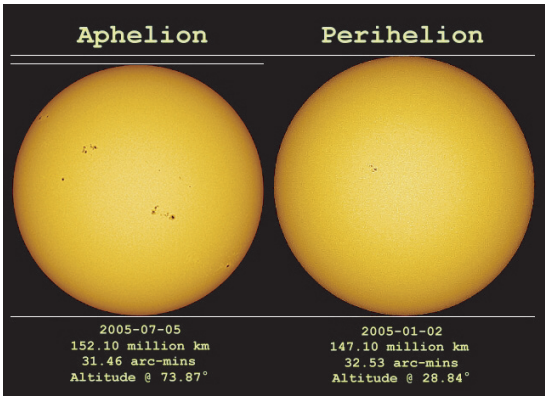

FIGURE 91 The angular size of the sun changes due to the elliptical motion of the Earth (© Anthony Ayiomamitis)

to the more than 20 *ice ages* in the last 2 million years. This happens through stronger or weaker irradiation of the poles by the Sun. The changing amounts of melted ice then lead to changes in average temperature. The last ice age had is peak about 20 000 years ago and ended around 11 800 years ago; the next is still far away. A spectacular confirmation of the

due to the interaction between precession and perihelion shift.

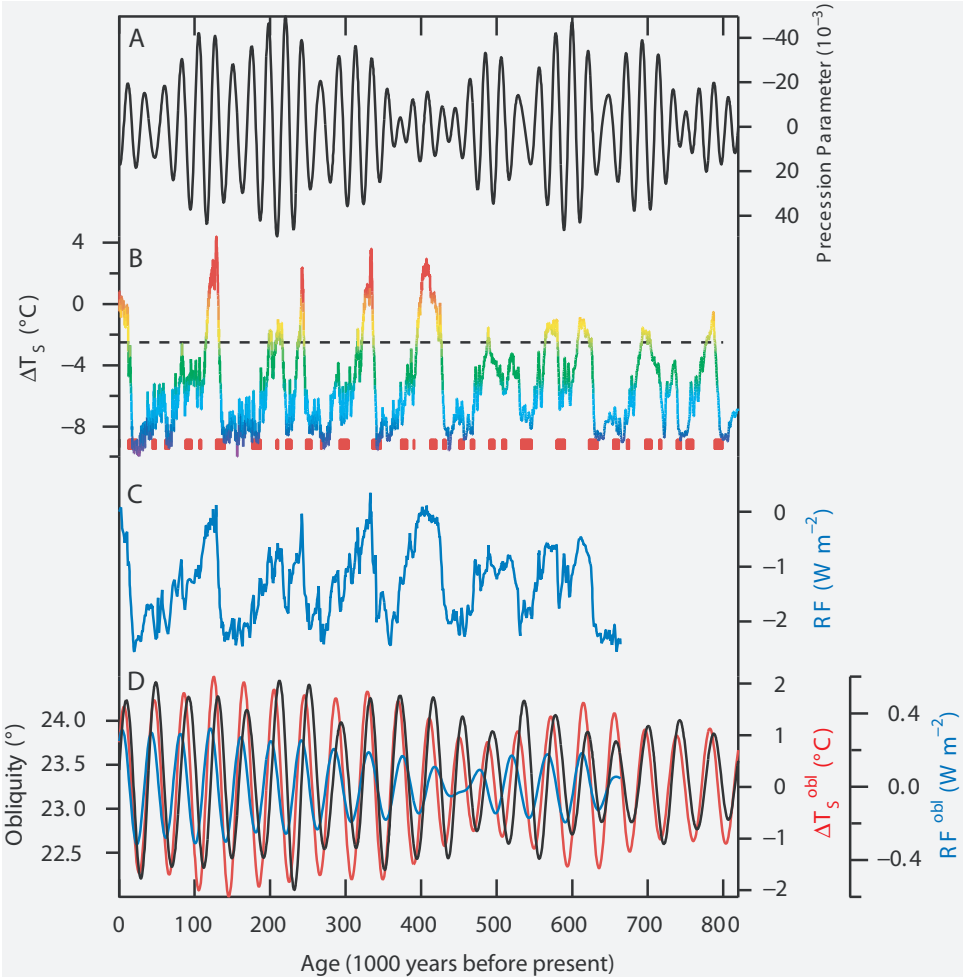

FIGURE 92 Modern measurements showing how Earth's precession parameter (black curve A) and obliquity (black curve D) influence the average temperature (coloured curve B) and the irradiation of the Earth (blue curve C) over the past 800 000 years: the obliquity deduced by Fourier analysis from the irradiation data RF (blue curve D) and the obliquity deduced by Fourier analysis from the temperature (red curve D) match the obliquity known from astronomical data (black curve D); sharp cooling events took place whenever the obliquity rose while the precession parameter was falling (marked red below the temperature curve) (© Jean Jouzel/Science from Ref. 98)

relation between ice age cycles and astronomy came through measurements of oxygen isotope ratios in ice cores and sea sediments, which allow the average temperature over the past million years to be tracked. Figure 92 shows how closely the temperature follows the changes in irradiation due to changes in obliquity and precession. Ref. 98

The Earth's orbit also changes its *eccentricity* with time, from completely circular to slightly oval and back. However, this happens in very complex ways, not with periodic regularity, and is due to the influence of the large planets of the solar system on the Earth's orbit. The typical time scale is 100 000 to 125 000 years.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

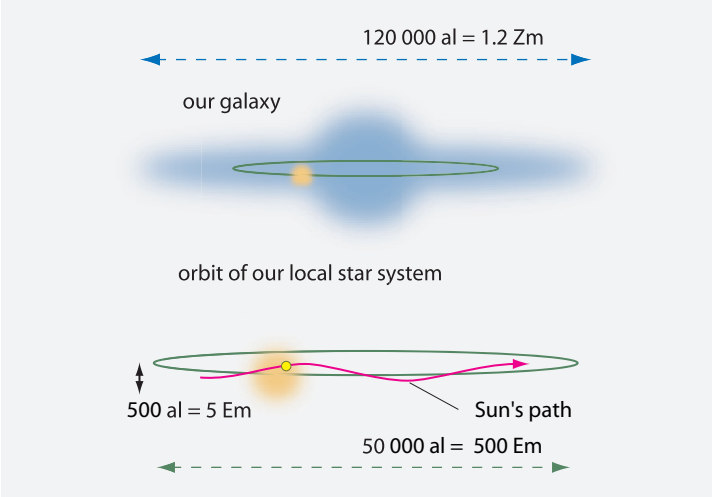

FIGURE 93 The motion of the Sun around the galaxy

In addition, the Earth's orbit changes in *inclination* with respect to the orbits of the other planets; this seems to happen regularly every 100 000 years. In this period the inclination changes from +2.5° to −2.5° and back.

Even the direction in which the ellipse points changes with time. This so-called *perihelion shift* is due in large part to the influence of the other planets; a small remaining part will be important in the chapter on general relativity. It was the first piece of data confirming the theory.

Obviously, the length of the year also changes with time. The measured variations are of the order of a few parts in 10^{11} or about 1 ms per year. However, knowledge of these changes and of their origins is much less detailed than for the changes in the Earth's rotation.

The next step is to ask whether the Sun itself moves. Indeed it does. Locally, it moves with a speed of 19.4 km/s towards the constellation of Hercules. This was shown by William Herschel in 1783. But globally, the motion is even more interesting. The diameter of the galaxy is at least 100 000 light years, and we are located 26 000 light years from the centre. (This has been known since 1918; the centre of the galaxy is located in the direction of Sagittarius.) At our position, the galaxy is 1 300 light years thick; presently, we are 68 light years 'above' the centre plane. The Sun, and with it the solar system, takes about 225 million years to turn once around the galactic centre, its orbital velocity being around 220 km/s. It seems that the Sun will continue moving away from the galaxy plane until it is about 250 light years above the plane, and then move back, as shown in Figure 93. The oscillation period is estimated to be around 62 million years, and has been suggested as the mechanism for the mass extinctions of animal life on Earth, possibly because some gas cloud or some cosmic radiation source may be periodically encountered on the way. The issue is still a hot topic of research.

Ref. 99

We turn around the galaxy centre because the formation of galaxies, like that of solar systems, always happens in a whirl. By the way, can you confirm from your own observation that our galaxy itself rotates?

Challenge 219 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Finally, we can ask whether the galaxy itself moves. Its motion can indeed be observed because it is possible to give a value for the motion of the Sun through the universe, defining it as the motion against the background radiation. This value has been measured to be 370 km/s. (The velocity of the *Earth* through the background radiation of course depends on the season.) This value is a combination of the motion of the Sun around the galaxy centre and of the motion of the galaxy itself. This latter motion is due to the gravitational attraction of the other, nearby galaxies in our local group of galaxies.*

Ref. 100

In summary, the Earth really moves, and it does so in rather complex ways. As Henri Poincaré would say, if we are in a given spot today, say the Panthéon in Paris, and come back to the same spot tomorrow at the same time, we are in fact 31 million kilometres away. This state of affairs would make time travel extremely difficult even if it were possible (which it is not); whenever you went back to the past, you would have to get to the old spot exactly!

Is velocity absolute? – The theory of everyday relativity

Why don't we feel all the motions of the Earth? The two parts of the answer were already given in 1632. First of all, as Galileo explained, we do not feel the accelerations of the Earth because the effects they produce are too small to be detected by our senses. Indeed, many of the mentioned accelerations do induce measurable effects only in high-precision experiments, e.g. in atomic clocks.

Page 515

But the second point made by Galileo is equally important: it is impossible to feel that we are moving. We do not feel translational, unaccelerated motions because this is impossible *in principle*. Galileo discussed the issue by comparing the observations of two observers: one on the ground and another on the most modern means of unaccelerated transportation of the time, a ship. Galileo asked whether a man on the ground and a man in a ship moving at constant speed experience (or 'feel') anything different. Einstein used observers in trains. Later it became fashionable to use travellers in rockets. (What will come next?) Galileo explained that only *relative* velocities between bodies produce effects, not the absolute values of the velocities. For the senses, there is no difference between constant, undisturbed motion, however rapid it may be, and rest. This is now called *Galileo's principle of relativity*. In everyday life we feel motion only if the means of transportation trembles (thus if it accelerates), or if we move against the air. Therefore Galileo concludes that two observers in straight and undisturbed motion against each other cannot say who is 'really' moving. Whatever their relative speed, neither of them 'feels' in motion.**

Challenge 220 e

* This is roughly the end of the ladder. Note that the expansion of the universe, to be studied later, produces no motion.

** In 1632, in his *Dialogo*, Galileo writes: 'Shut yourself up with some friend in the main cabin below decks on some large ship, and have with you there some flies, butterflies, and other small flying animals. Have a large bowl of water with some fish in it; hang up a bottle that empties drop by drop into a wide vessel beneath it. With the ship standing still, observe carefully how the little animals fly with equal speed to all sides of the cabin. The fish swim indifferently in all directions; the drops fall into the vessel beneath; and, in throwing something to your friend, you need throw it no more strongly in one direction than another, the distances being equal: jumping with your feet together, you pass equal spaces in every direction. When you have observed all these things carefully (though there is no doubt that when the ship is standing still everything must happen in this way), have the ship proceed with any speed you like, so long as the motion

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Rest is relative. Or more clearly: rest is an observer-dependent concept. This result of Galilean physics is so important that Poincaré introduced the expression 'theory of relativity' and Einstein repeated the principle explicitly when he published his famous theory of special relativity. However, these names are awkward. Galilean physics is also a theory of relativity! The relativity of rest is common to *all* of physics; it is an essential aspect of motion.

Undisturbed or uniform motion has no observable effect; only *change* of motion does. As a result, every physicist can deduce something simple about the following statement by Wittgenstein:

> Daß die Sonne morgen aufgehen wird, ist eine Hypothese; und das heißt: wir *wissen* nicht, ob sie aufgehen wird.*

The statement is *wrong*. Can you explain why Wittgenstein erred here, despite his strong desire not to?

Challenge 221 s

Is rotation relative?

When we turn rapidly, our arms lift. Why does this happen? How can our body detect whether we are rotating or not? There are two possible answers. The first approach, promoted by Newton, is to say that there is an absolute space; whenever we rotate against this space, the system reacts. The other answer is to note that whenever the arms lift, the stars also rotate, and in exactly the same manner. In other words, our body detects rotation because we move against the average mass distribution in space.

The most cited discussion of this question is due to Newton. Instead of arms, he explored the water in a rotating bucket. As usual for philosophical issues, Newton's answer was guided by the mysticism triggered by his father's early death. Newton saw absolute space as a religious concept and was not even able to conceive an alternative. Newton

is uniform and not fluctuating this way and that, you will discover not the least change in all the effects named, nor could you tell from any of them whether the ship was moving or standing still. In jumping, you will pass on the floor the same spaces as before, nor will you make larger jumps toward the stern than toward the prow even though the ship is moving quite rapidly, despite the fact that during the time you are in the air the floor under you will be going in a direction opposite to your jump. In throwing something to your companion, you will need no more force to get it to him whether he is in the direction of the bow or the stern, with yourself situated opposite. The droplets will fall as before into the vessel beneath without dropping toward the stern, although while the drops are in the air the ship runs many spans. The fish in their water will swim toward the front of their bowl with no more effort than toward the back, and will go with equal ease to bait placed anywhere around the edges of the bowl. Finally the butterflies and flies will continue their flights indifferently toward every side, nor will it ever happen that they are concentrated toward the stern, as if tired out from keeping up with the course of the ship, from which they will have been separated during long intervals by keeping themselves in the air. And if smoke is made by burning some incense, it will be seen going up in the form of a little cloud, remaining still and moving no more toward one side than the other. The cause of all these correspondences of effects is the fact that the ship's motion is common to all the things contained in it, and to the air also. That is why I said you should be below decks; for if this took place above in the open air, which would not follow the course of the ship, more or less noticeable differences would be seen in some of the effects noted.'

* 'That the Sun will rise to-morrow, is an hypothesis; and that means that we do not *know* whether it will rise.' This well-known statement is found in Ludwig Wittgenstein, *Tractatus*, 6.36311.

thus sees rotation as an absolute concept. Most modern scientist have fewer problems and more common sense than Newton; as a result, today's consensus is that rotation effects are due to the mass distribution in the universe: rotation is relative. However, we have to be honest; the question cannot be settled by Galilean physics. We will need general relativity.

Curiosities and fun challenges about relativity

When travelling in the train, you can test Galileo's statement about everyday relativity of motion. Close your eyes and ask somebody to turn you around many times: are you able Challenge 222 e to say in which direction the train is running?

* *

A good bathroom scales, used to determine the weight of objects, does not show a con- Challenge 223 s stant weight when you step on it and stay motionless. Why not?

* *

Challenge 224 s If a gun located at the Equator shoots a bullet vertically, where does the bullet fall?

* *

Challenge 225 s Why are most rocket launch sites as near as possible to the Equator?

* *

Would travelling through interplanetary space be healthy? People often fantasize about long trips through the cosmos. Experiments have shown that on trips of long duration, cosmic radiation, bone weakening and muscle degeneration are the biggest dangers. Many medical experts question the viability of space travel lasting longer than a couple of years. Other dangers are rapid sunburn, at least near the Sun, and exposure to Ref. 101 the vacuum. So far only one man has experienced vacuum without protection. He lost consciousness after 14 seconds, but survived unharmed.

Challenge 226 s In which direction does a flame lean if it burns inside a jar on a rotating turntable?

* *

A ping-pong ball is attached by a string to a stone, and the whole is put under water in a jar. The set-up is shown in Figure 95. Now the jar is accelerated horizontally. In which Challenge 227 s direction does the ball move? What do you deduce for a jar at rest?

* *

Galileo's principle of everyday relativity states that it is impossible to determine an absolute velocity. It is equally impossible to determine an absolute position, an absolute time Challenge 228 ny and an absolute direction. Is this correct?

* *

Does centrifugal acceleration exist? Most university students go through the shock of meeting a teacher who says that it doesn't because it is a 'fictitious' quantity, in the face of what one experiences every day in a car when driving around a bend. Simply ask the teacher who denies it to define 'existence'. (The definition physicists usually use is given in Page 856 an upcoming chapter.) Then check whether the definition applies to the term and make Challenge 229 s up your own mind.

* *

Rotation holds a surprise for anybody who studies it carefully. Angular momentum is a quantity with a magnitude and a direction. However, it is not a vector, as any mirror shows. The angular momentum of a body circling in a plane parallel to a mirror behaves in a different way from a usual arrow: its mirror image is not reflected if it points towards Challenge 230 e the mirror! You can easily check this for yourself. For this reason, angular momentum is called a *pseudovector*. The fact has no important consequences in classical physics; but we have to keep it in mind for later occasions.

* *

What is the best way to transport a number of full coffee or tea cups while at the same Challenge 231 s time avoiding spilling any precious liquid?

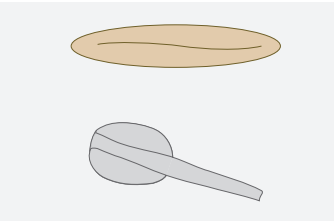

FIGURE 96 The famous Celtic stone and a version made with a spoon

from its energy E in joule via

$$M_s = \frac{\log(E/1\,\mathrm{J}) - 4.8}{1.5} \,. \tag{30}$$

The strange numbers in the expression have been chosen to put the earthquake values as near as possible to the older, qualitative Mercalli scale (now called EMS98) that classifies the intensity of earthquakes. However, this is not fully possible; the most sensitive instruments today detect earthquakes with magnitudes of −3. The highest value every measured was a Richter magnitude of 10, in Chile in 1960. Magnitudes above 12 are probably impossible. (Can you show why?)

Challenge 233 s

* *

Figure 96 shows the so-called *Celtic wiggle stone* (also called *wobblestone* or *rattleback*), a stone that starts rotating on a plane surface when it is put into oscillation. The size can vary between a few centimetres and a few metres. By simply bending a spoon one can realize a primitive form of this strange device, if the bend is not completely symmetrical. The rotation is always in the same direction. If the stone is put into rotation in the wrong direction, after a while it stops and starts rotating in the other sense! Can you explain the effect?

An impressive confirmation that the Earth is round can be seen at sunset, if one turns, against usual habits, one's back on the Sun. On the eastern sky one can see the impressive rise of the Earth's shadow. (In fact, more precise investigations show that it is not the shadow of the Earth alone, but the shadow of its ionosphere.) One can admire a vast shadow rising over the whole horizon, clearly having the shape of a segment of a huge circle.

* *

Challenge 247 s How would Figure 98 look if taken at the Equator?

* *

Since the Earth is round, there are many ways to drive from one point on the Earth to another along a circle segment. This has interesting consequences for volley balls and for girl-watching. Take a volleyball and look at its air inlet. If you want to move the inlet

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

to a different position with a simple rotation, you can choose the rotation axis in may
Challenge 248 e different ways. Can you confirm this? In other words, when we look in a given direction and then want to look in another, the eye can accomplish this change in different ways. The option chosen by the human eye had already been studied by medical scientists in the eighteenth century. It is called *Listing's 'law'*.* It states that all axes that nature chooses
Challenge 249 s lie in one plane. Can you imagine its position in space? Men have a real interest that this mechanism is strictly followed; if not, looking at girls on the beach could cause the muscles moving the eyes to get knotted up.

Legs or wheels? – Again

The acceleration and deceleration of standard wheel-driven cars is never much greater than about $1\,g = 9.8\,\mathrm{m/s^2}$, the acceleration due to gravity on our planet. Higher accelerations are achieved by motorbikes and racing cars through the use of suspensions that divert weight to the axes and by the use of spoilers, so that the car is pushed downwards with more than its own weight. Modern spoilers are so efficient in pushing a car towards the track that racing cars could race on the roof of a tunnel without falling down.

Through the use of special tyres these downwards forces are transformed into grip; modern racing tyres allow forward, backward and sideways accelerations (necessary for speed increase, for braking and for turning corners) of about 1.1 to 1.3 times the load. Engineers once believed that a factor 1 was the theoretical limit and this limit is still sometimes found in textbooks; but advances in tyre technology, mostly by making clever use of interlocking between the tyre and the road surface as in a gear mechanism, have allowed engineers to achieve these higher values. The highest accelerations, around $4\,g$, are achieved when part of the tyre melts and glues to the surface. Special tyres designed to make this happen are used for dragsters, but high performance radio-controlled model cars also achieve such values.

How do all these efforts compare to using legs? High jump athletes can achieve peak accelerations of about 2 to 4 g, cheetahs over $3\,g$, bushbabies up to $13\,g$, locusts about
Ref. 102 $18\,g$, and fleas have been measured to accelerate about $135\,g$. The maximum acceleration known for animals is that of click beetles, a small insect able to accelerate at over $2000\,\mathrm{m/s^2} = 200\,g$, about the same as an airgun pellet when fired. Legs are thus definitively more efficient accelerating devices than wheels – a cheetah can easily beat any car or motorbike – and evolution developed legs, instead of wheels, to improve the chances of an animal in danger getting to safety. In short, legs *outperform* wheels.

Challenge 250 s There are other reasons for using legs instead of wheels. (Can you name some?) For example, legs, unlike wheels, allow walking on water. Most famous for this ability is the *basilisk*,** a lizard living in Central America. This reptile is about 50 cm long and has a mass of about 90 g. It looks like a miniature *Tyrannosaurus rex* and is able to run over water surfaces on its hind legs. The motion has been studied in detail with high-speed cameras and by measurements using aluminium models of the animal's feet. The experi-

* If you are interested in learning in more detail how nature and the eye cope with the complexities of three dimensions, see the schorlab.berkeley.edu/vilis/whatisLL.htm and www.med.uwo.ca/physiology/courses/LLConsequencesWeb/ListingsLaw/perceptual2.htm websites.

** In the Middle Ages, the term 'basilisk' referred to a mythical monster supposed to appear shortly before the end of the world. Today, it is a small reptile in the Americas.

FIGURE 99 A basilisk lizard (*Basiliscus basiliscus*) running on water, with a total length of about 25 cm, showing how the propulsing leg pushes into the water (© TERRA)

FIGURE 100 A water strider, total size about 10 mm (© Charles Lewallen)

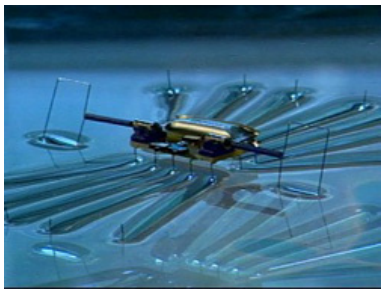

FIGURE 101 A water walking robot, total size about 20 mm (© AIP)

ments show that the feet slapping on the water provides only 25 % of the force necessary
Ref. 103 to run above water; the other 75 % is provided by a pocket of compressed air that the basilisks create between their feet and the water once the feet are inside the water. In fact, basilisks mainly walk on air. (Both effects used by basilisks are also found in fast
Ref. 104 canoeing.) It was calculated that humans are also able to walk on water, provided their feet hit the water with a speed of 100 km/h using the simultaneous physical power of 15 sprinters. Quite a feat for all those who ever did so.

There is a second method of walking and running on water; this second method even allows its users to remain immobile on top of the water surface. This is what water striders, insects of the family *Gerridae* with a overall length of up to 15 mm, are able to do (together with several species of spiders). Like all insects, the water strider has six legs (spiders have eight). The water strider uses the back and front legs to hover over the surface, helped by thousands of tiny hairs attached to its body. The hairs, together with the surface tension of water, prevent the strider from getting wet. If you put shampoo into the water, the water strider sinks and can no longer move. The water strider uses its large middle legs as oars to advance over the surface, reaching speeds of up to 1 m/s doing so. In short, water striders actually row over water. The same mechanism is used by the
Ref. 105 small robots that can move over water and were developed by Metin Sitti and his group.

Legs pose many interesting problems. Engineers know that a staircase is comfortable to walk only if for each step the depth l plus *twice* the height h is a constant: $l + 2h =$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 251 s 0.63 ± 0.02 m. This is the so-called *staircase formula*. Why does it hold?

Challenge 252 s All animals have an *even* number of legs. Do you know an exception? Why not? In fact, one can argue that no animal has less than four legs. Why is this the case?

On the other hand, all animals with two legs have the legs side by side, whereas systems with two wheels have them one behind the other. Why is this not the other way round? Challenge 253 e

Legs also provide simple distance rulers: just count your steps. In 2006, it was discovered that this method is used by certain ant species, such as *Cataglyphis fortis*. They can count to at least 25 000, as shown by Matthias Wittlinger and his team. These ants use the ability to find the shortest way back to their home even in structureless desert terrain. Ref. 106

Why do 100 m sprinters run faster than ordinary people? A thorough investigation shows that the speed v of a sprinter is given by Ref. 107

$$v = f\, L_{\text{stride}} = f\, L_{\text{c}}\, \frac{F_{\text{c}}}{W}\,, \tag{31}$$

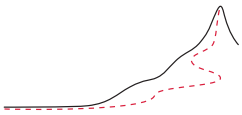
where f is the frequency of the legs, L_{stride} is the stride length, L_{c} is the contact length – the length that the sprinter advances during the time the foot is in contact with the floor – W the weight of the sprinter, and F_{c} the average force the sprinter exerts on the floor during contact. It turns out that the frequency f is almost the same for all sprinters; the only way to be faster than the competition is to increase the stride length L_{stride}. Also the contact length L_{c} varies little between athletes. Increasing the stride length thus requires that the athlete hits the ground with strong strokes. This is what athletic training for sprinters has to achieve.

Summary on Galilean relativity

Undisturbed or inertial motion cannot be felt or measured. It is thus impossible to distinguish motion from rest; the distinction depends on the observer: motion of bodies is relative. That is why the soil below our feet seems so stable to us, even though it moves with high speed across the universe.

Only later on will we discover that one example of motion in nature is *not* relative: the motion of light. But first we continue first with the study of motion transmitted over distance, without the use of any contact at all.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 6

MOTION DUE TO GRAVITATION

> Caddi come corpo morto cade.
>
> Dante, *Inferno*, c. V, v. 142.*

The first and main contact-free method to generate motion we discover in our environment is *height*. Waterfalls, snow, rain and falling apples all rely on it. It was one of the fundamental discoveries of physics that height has this property because there is an interaction between every body and the Earth. *Gravitation* produces an acceleration along the line connecting the centres of gravity of the body and the Earth. Note that in order to make this statement, it is necessary to realize that the Earth is a body in the same way as a stone or the Moon, that this body is finite and that therefore it has a centre and a mass. Today, these statements are common knowledge, but they are by no means evident from everyday personal experience.**

How does gravitation change when two bodies are far apart? The experts on distant objects are the astronomers. Over the years they have performed numerous measurements of the movements of the Moon and the planets. The most industrious of all was Tycho Brahe,*** who organized an industrial-scale search for astronomical facts sponsored by his king. His measurements were the basis for the research of his young assistant, the Swabian astronomer Johannes Kepler**** who found the first precise description of planetary motion. In 1684, all observations of planets and stones were condensed into an

Page 856

* 'I fell like dead bodies fall.' Dante Alighieri (1265, Firenze–1321, Ravenna), the powerful Italian poet.

** In several myths about the creation or the organization of the world, such as the biblical one or the Indian one, the Earth is not an object, but an imprecisely defined entity, such as an island floating or surrounded by water with unclear boundaries and unclear method of suspension. Are you able to convince a friend that the Earth is round and not flat? Can you find another argument apart from the roundness of the Earth's shadow when it is visible on the Moon?

Challenge 254 s

Ref. 108

A famous crook, Robert Peary, claimed to have reached the North Pole in 1909. (In fact, Roald Amundsen reached the both the South and the North Pole first.) Among others, Peary claimed to have taken a picture there, but that picture, which went round the world, turned out to be one of the proofs that he had not been there. Can you imagine how?

Challenge 255 s

By the way, if the Earth is round, the top of two buildings is further apart than their base. Can this effect be measured?

Challenge 256 s

*** Tycho Brahe (1546–1601), famous Danish astronomer, builder of Uraniaborg, the astronomical castle. He consumed almost 10 % of the Danish gross national product for his research, which produced the first star catalogue and the first precise position measurements of planets.

**** Johannes Kepler (1571 Weil der Stadt–1630 Regensburg) studied Protestant theology and became a teacher of mathematics, astronomy and rhetoric. He helped his mother to defend herself successfully in a trial where she was accused of witchcraft. His first book on astronomy made him famous, and he became

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 102 How to compare the radius of the Earth with that of the Moon during a partial lunar eclipse (© Anthony Ayiomamitis)

astonishingly simple result by the English physicist Robert Hooke:* every body of mass M attracts any other body towards its centre with an acceleration whose magnitude a is given by

$$a = G\frac{M}{r^2} \tag{32}$$

where r is the centre-to-centre distance of the two bodies. This is called the *universal 'law' of gravitation*, or universal gravity, because it is valid in general. The proportionality constant G is called the *gravitational constant*; it is one of the fundamental constants of nature, like the speed of light or the quantum of action. More about it will be said shortly. The effect of gravity thus decreases with increasing distance; gravity depends on the inverse distance squared of the bodies under consideration. If bodies are small compared with the distance r, or if they are spherical, expression (32) is correct as it stands; for non-spherical shapes the acceleration has to be calculated separately for each part of the bodies and then added together.

This inverse square dependence is often called Newton's 'law' of gravitation, because the English physicist Isaac Newton proved more elegantly than Hooke that it agreed with all astronomical and terrestrial observations. Above all, however, he organized a better public relations campaign, in which he falsely claimed to be the originator of the idea. Ref. 109

Newton published a simple proof showing that this description of astronomical motion also gives the correct description for stones thrown through the air, down here on 'father Earth'. To achieve this, he compared the acceleration a_m of the Moon with that of stones g. For the ratio between these two accelerations, the inverse square relation predicts a value $a_m/g = R^2/d_m^2$, where R is the radius of the Earth and d_m the distance of the Moon. The Moon's distance can be measured by triangulation, comparing the pos-

assistant to Tycho Brahe and then, at his teacher's death, the Imperial Mathematician. He was the first to use mathematics in the description of astronomical observations, and introduced the concept and field of 'celestial physics'.

* Robert Hooke, (1635–1703), important English physicist and secretary of the Royal Society. Apart from discovering the inverse square relation and many others, such as Hooke's 'law', he also wrote the *Micrographia*, a beautifully illustrated exploration of the world of the very small.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ition of the Moon against the starry background from two different points on Earth.* The result is $d_m/R = 60 \pm 3$, depending on the orbital position of the Moon, so that an average ratio $a_m/g = 3.6 \cdot 10^3$ is predicted from universal gravity. But both accelerations can also be measured directly. At the surface of the Earth, stones are subject to an acceleration due to gravitation with magnitude $g = 9.8\,\mathrm{m/s^2}$, as determined by measuring the time that stones need to fall a given distance. For the Moon, the definition of acceleration, $a = \mathrm{d}v/\mathrm{d}t$, in the case of circular motion – roughly correct here – gives $a_m = d_m(2\pi/T)^2$, where $T = 2.4\,\mathrm{Ms}$ is the time the Moon takes for one orbit around the Earth.** The measurement of the radius of the Earth*** yields $R = 6.4\,\mathrm{Mm}$, so that the average Earth–Moon distance is $d_m = 0.38\,\mathrm{Gm}$. One thus has $a_m/g = 3.6 \cdot 10^3$, in agreement with the above prediction. With this famous 'Moon calculation' we have thus shown that the inverse square property of gravitation indeed describes both the motion of the Moon and that of stones. You might want to deduce the value of GM.

Challenge 260 s

From the observation that on the Earth all motion eventually comes to rest, whereas in the sky all motion is eternal, Aristotle and many others had concluded that motion in the sublunar world has different properties from motion in the translunar world. Several thinkers had criticized this distinction, notably the French philosopher and rector of the University of Paris, Jean Buridan.**** The Moon calculation was the most important result showing this distinction to be wrong. This is the reason for calling the expression (32) the *universal* 'law' of gravitation.

Ref. 112

This result allows us to answer another old question. Why does the Moon not fall from the sky? Well, the preceding discussion showed that *fall* is motion due to gravitation. Therefore the Moon actually *is* falling, with the peculiarity that instead of falling *towards* the Earth, it is continuously falling *around* it. Figure 103 illustrates the idea. The Moon is continuously missing the Earth.*****

* The first precise – but not the first – measurement was achieved in 1752 by the French astronomers Lalande and La Caille, who simultaneously measured the position of the Moon seen from Berlin and from Le Cap.

** This is deduced easily by noting that for an object in circular motion, the magnitude v of the velocity $\boldsymbol{v} = \mathrm{d}\boldsymbol{x}/\mathrm{d}t$ is given as $v = 2\pi r/T$. The drawing of the vector $\boldsymbol{v}$ over time, the so-called *hodograph*, shows that it behaves exactly like the position of the object. Therefore the magnitude a of the acceleration $\boldsymbol{a} = \mathrm{d}\boldsymbol{v}/\mathrm{d}t$ is given by the corresponding expression, namely $a = 2\pi v/T$.

Challenge 257 s

*** This is the hardest quantity to measure oneself. The most surprising way to determine the Earth's size is the following: watch a sunset in the garden of a house, with a stopwatch in hand. When the last ray of the Sun disappears, start the stopwatch and run upstairs. There, the Sun is still visible; stop the stopwatch when the Sun disappears again and note the time t. Measure the height distance h of the two eye positions where the Sun was observed. The Earth's radius R is then given by $R = k\,h/t^2$, with $k = 378 \cdot 10^6\,\mathrm{s^2}$.

Ref. 110

Challenge 258 s

There is also a simple way to measure the distance to the Moon, once the size of the Earth is known. Take a photograph of the Moon when it is high in the sky, and call θ its zenith angle, i.e., its angle from the vertical. Make another photograph of the Moon a few hours later, when it is just above the horizon. On this picture, unlike a common optical illusion, the Moon is smaller, because it is further away. With a sketch the reason for this becomes immediately clear. If q is the ratio of the two angular diameters, the Earth–Moon distance d_m is given by the relation $d_m^2 = R^2 + (2Rq\cos\theta/(1-q^2))^2$. Enjoy finding its derivation from the sketch.

Ref. 111

Page 69

Challenge 259 s

Another possibility is to determine the size of the Moon by comparing it with the size of the shadow of the Earth during a lunar eclipse, as shown in Figure 102. The distance to the Moon is then computed from its angular size, about 0.5°.

**** Jean Buridan (*c.* 1295 to *c.* 1366) was also one of the first modern thinkers to discuss the rotation of the Earth about an axis.

***** Another way to put it is to use the answer of the Dutch physicist Christiaan Huygens (1629–1695):

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 103 A physicist's and an artist's view of the fall of the Moon: a diagram by Christiaan Huygens (not to scale) and a marble statue by Auguste Rodin

FIGURE 104 A precision second pendulum, thus about 1 m in length; almost at the upper end, the vacuum chamber that compensates for changes in atmospheric pressure; towards the lower end, the wide construction that compensates for temperature variations of pendulum length; at the very bottom, the screw that compensates for local variations of the gravitational acceleration, giving a final precision of about 1 s per month (© Erwin Sattler OHG)

Universal gravity also explains why the Earth and most planets are (almost) spherical. Since gravity increases with decreasing distance, a liquid body in space will always try to form a spherical shape. Seen on a large scale, the Earth is indeed liquid. We also know that the Earth is cooling down – that is how the crust and the continents formed. The

the Moon does not fall from the sky because of the centrifugal acceleration. As explained on page 135, this explanation is nowadays out of favour at most universities.

Ref. 113 Challenge 261 d There is a beautiful problem connected to the left part of the figure: Which points on the surface of the Earth can be hit by shooting from a mountain? And which points can be hit by shooting horizontally?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

sphericity of smaller solid objects encountered in space, such as the Moon, thus means that they used to be liquid in older times.

Properties of gravitation

Gravitation implies that the path of a stone is not a parabola, as stated earlier, but actually an ellipse around the centre of the Earth. This happens for exactly the same reason that the planets move in ellipses around the Sun. Are you able to confirm this statement?

Challenge 262 ny

Universal gravitation allows us to solve a mystery. The puzzling acceleration value $g = 9.8\,\mathrm{m/s^2}$ we encountered in equation (5) is thus due to the relation

$$g = GM_{\mathrm{Earth}}/R^2_{\mathrm{Earth}} \,. \tag{33}$$

The equation can be deduced from equation (32) by taking the Earth to be spherical. The everyday acceleration of gravity g thus results from the size of the Earth, its mass, and the universal constant of gravitation G. Obviously, the value for g is almost constant on the surface of the Earth because the Earth is almost a sphere. Expression (33) also explains why g gets smaller as one rises above the Earth, and the deviations of the shape of the Earth from sphericity explain why g is different at the poles and higher on a plateau. (What would it be on the Moon? On Mars? On Jupiter?)

Challenge 263 s

By the way, it is possible to devise a simple machine, other than a yo-yo, that slows down the effective acceleration of gravity by a known amount, so that one can measure its value more easily. Can you imagine it?

Challenge 264 s

Note that 9.8 is roughly π^2. This is *not* a coincidence: the metre has been chosen in such a way to make this (roughly) correct. The period T of a swinging pendulum, i.e., a back and forward swing, is given by*

Challenge 265 s

$$T = 2\pi\sqrt{\frac{l}{g}} \,, \tag{34}$$

where l is the length of the pendulum, and $g = 9.8\,\mathrm{m/s^2}$ is the gravitational acceleration. (The pendulum is assumed to consist of a compact mass attached to a string of negligible mass.) The oscillation time of a pendulum depends only on the length of the string and on g, thus on the planet it is located on.

If the metre had been defined such that $T/2 = 1\,\mathrm{s}$, the value of the normal acceleration g would have been exactly $\pi^2\,\mathrm{m/s^2}$. Indeed, this was the first proposal for the definition of the metre; it was made in 1673 by Huygens and repeated in 1790 by Talleyrand, but was rejected by the conference that defined the metre because variations in the value of g with

Challenge 267 e

* Formula (34) is noteworthy mainly for all that is missing. The period of a pendulum does *not* depend on the mass of the swinging body. In addition, the period of a pendulum does *not* depend on the amplitude. (This is true as long as the oscillation angle is smaller than about 15°.) Galileo discovered this as a student, when observing a chandelier hanging on a long rope in the dome of Pisa. Using his heartbeat as a clock he found that even though the amplitude of the swing got smaller and smaller, the time for the swing stayed the same.

A leg also moves like a pendulum, when one walks normally. Why then do taller people tend to walk faster? Is the relation also true for animals of different size?

Challenge 266 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 105 The measurements that lead to the definition of the metre (© Ken Alder)

geographical position, temperature-induced variations of the length of a pendulum and even air pressure variations induce errors that are too large to yield a definition of useful precision. (Indeed, all these effects must be corrected in pendulum clocks, as shown in Figure 104.)

Finally, the proposal was made to define the metre as 1/40 000 000 of the circumference of the Earth through the poles, a so-called *meridian*. This proposal was almost identical to – but much more precise than – the pendulum proposal. The meridian definition of the metre was then adopted by the French national assembly on 26 March 1791, with the statement that 'a meridian passes under the feet of every human being, and all meridians are equal'. (Nevertheless, the distance from Equator to the poles is not exactly 10 Mm; that is a strange story. One of the two geographers who determined the size of the first metre stick was dishonest. The data he gave for his measurements – the general method of which is shown in Figure 105 – was fabricated. Thus the first official metre stick in Paris was shorter than it should be.)

Ref. 114

But we can still ask: Why does the Earth have the mass and size it has? And why does G have the value it has? The first question asks for a history of the solar system; it is still unanswered and is topic of research. The second question is addressed in Appendix C.

If all objects attract each other, it should also be the case for objects in everyday life. Gravity must also work *sideways*. This is indeed the case, even though the effects are so small that they were measured only long after universal gravity had predicted them. Measuring this effect allows the gravitational constant G to be determined.

Note that measuring the gravitational constant G is also the only way to determine the mass of the *Earth*. The first to do so, in 1798, was the English physicist Henry Cavendish; he used the machine, ideas and method of John Michell who died when attempting

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

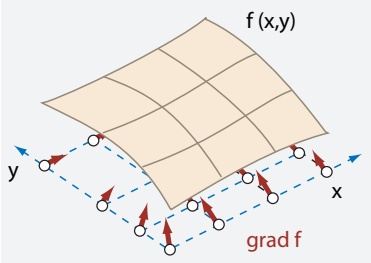


FIGURE 106 The potential and the gradient

the experiment. Michell and Cavendish* called the aim and result of their experiments 'weighing the Earth'. Are you able to imagine how they did it? The value found in modern experiments is

Challenge 268 s

$$G = 6.7 \cdot 10^{-11}\,\mathrm{Nm^2/kg^2} = 6.7 \cdot 10^{-11}\,\mathrm{m^3/kg\,s^2}\ . \tag{35}$$

Cavendish's experiment was thus the first to confirm that gravity also works sideways.

For example, two average people 1 m apart feel an acceleration towards each other that is less than that exerted by a common fly when landing on the skin. Therefore we usually do not notice the attraction to other people. When we notice it, it is much stronger than that. This simple calculation thus proves that gravitation cannot be the true cause of people falling in love, and that sexual attraction is not of gravitational origin, but of a different source. The basis for this other interaction, love, will be studied later in our walk: it is called *electromagnetism*.

Challenge 269 s

But gravity has more interesting properties to offer. The effects of gravitation can also be described by another observable, namely the *(gravitational) potential* φ. We then have the simple relation that the acceleration is given by the *gradient* of the potential

$$\boldsymbol{a} = -\nabla\varphi \qquad \text{or} \qquad \boldsymbol{a} = -\mathrm{grad}\,\varphi\ . \tag{36}$$

The gradient is just a learned term for 'slope along the steepest direction'. It is defined for any point on a slope, is large for a steep one and small for a shallow one and it points in the direction of steepest ascent, as shown in Figure 106. The gradient is abbreviated ∇, pronounced 'nabla' and is mathematically defined as the vector $\nabla\varphi = (\partial\varphi/\partial x, \partial\varphi/\partial y, \partial\varphi/\partial z) = \mathrm{grad}\,\varphi$. The minus sign in (36) is introduced by convention, in order to have higher potential values at larger heights.** For a point-like or a spherical body of mass M, the potential φ is

$$\varphi = -G\frac{M}{r}\ . \tag{37}$$

A potential considerably simplifies the description of motion, since a potential is additive:

* Henry Cavendish (1731–1810) was one of the great geniuses of physics; rich but solitary, he found many rules of nature, but never published them. Had he done so, his name would be much more well known. John Michell (1724–1793) was church minister, geologist and amateur astronomer.

** In two or more dimensions slopes are written $\partial\varphi/\partial z$ – where ∂ is still pronounced 'd' – because in those cases the expression $d\varphi/dz$ has a slightly different meaning. The details lie outside the scope of this walk.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

given the potential of a point particle, one can calculate the potential and then the motion around any other irregularly shaped object.*

The potential φ is an interesting quantity; with a single number at every position in space we can describe the vector aspects of gravitational acceleration. It automatically gives that gravity in New Zealand acts in the opposite direction to gravity in Paris. In addition, the potential suggests the introduction of the so-called *potential energy* U by setting

$$U = m\varphi \tag{39}$$

and thus allowing us to determine the change of *kinetic* energy T of a body falling from a point 1 to a point 2 via

$$T_1 - T_2 = U_2 - U_1 \qquad \text{or} \qquad \frac{1}{2}m_1 \boldsymbol{v}_1^2 - \frac{1}{2}m_2 \boldsymbol{v}_2^2 = m\varphi_2 - m\varphi_1 \,. \tag{40}$$

In other words, the total energy, defined as the sum of kinetic and potential energy, is *conserved* in motion due to gravity. This is a characteristic property of gravitation. Not all accelerations can be derived from a potential; systems with this property are called *conservative*. The accelerations due to friction are not conservative, but those due to electromagnetism are.

Challenge 271 s Interestingly, the number of dimensions of space d is coded into the potential of a spherical mass: its dependence on the radius r is in fact $1/r^{d-2}$. The exponent $d-2$ has been checked experimentally to high precision; no deviation of d from 3 has ever been found.

Ref. 115

Ref. 116 The concept of potential helps in understanding the *shape* of the Earth. Since most of the Earth is still liquid when seen on a large scale, its surface is always horizontal with respect to the direction determined by the combination of the accelerations of gravity and rotation. In short, the Earth is *not* a sphere. It is not an ellipsoid either. The mathematical

Ref. 117 shape defined by the equilibrium requirement is called a *geoid*. The geoid shape differs from a suitably chosen ellipsoid by at most 50 m. Can you describe the geoid mathematically?

Challenge 272 ny The geoid is an excellent approximation to the actual shape of the Earth; sea level

* Alternatively, for a general, extended body, the potential is found by requiring that the *divergence* of its gradient is given by the mass (or charge) density times some proportionality constant. More precisely, one has

$$\Delta\varphi = 4\pi G\rho \tag{38}$$

where $\rho = \rho(\boldsymbol{x}, t)$ is the mass volume density of the body and the operator Δ, pronounced 'delta', is defined as $\Delta f = \nabla\nabla f = \partial^2 f/\partial x^2 + \partial^2 f/\partial y^2 + \partial^2 f/\partial z^2$. Equation (38) is called the *Poisson equation* for the potential φ. It is named after Siméon-Denis Poisson (1781–1840), eminent French mathematician and physicist. The positions at which ρ is not zero are called the *sources* of the potential. The so-called source term $\Delta\varphi$ of a function is a measure for how much the function $\varphi(x)$ at a point x differs from the average value in a

Challenge 270 ny region around that point. (Can you show this, by showing that $\Delta\varphi \approx \bar{\varphi} - \varphi(x)$?) In other words, the Poisson equation (38) implies that the actual value of the potential at a point is the same as the average value around that point minus the mass density multiplied by $4\pi G$. In particular, in the case of empty space the potential at a point is equal to the average of the potential around that point.

Often the concept of *gravitational field* is introduced, defined as $\boldsymbol{g} = -\nabla\varphi$. We avoid this in our walk, because we will discover that, following the theory of relativity, gravity is not due to a field at all; in fact even the concept of gravitational potential turns out to be only an approximation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

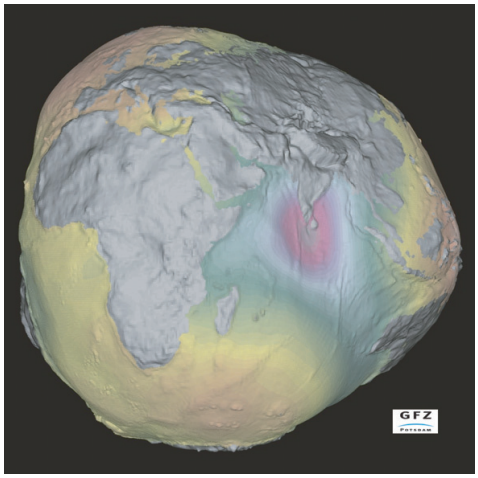

FIGURE 107 The shape of the Earth, with exaggerated height scale (© GeoForschungsZentrum Potsdam)

differs from it by less than 20 metres. The differences can be measured with satellite radar and are of great interest to geologists and geographers. For example, it turns out that the South Pole is nearer to the equatorial plane than the North Pole by about 30 m. This is probably due to the large land masses in the northern hemisphere.

Page 117

Above we saw how the inertia of matter, through the so-called 'centrifugal force', increases the radius of the Earth at the Equator. In other words, the Earth is *flattened* at the poles. The Equator has a radius a of 6.38 Mm, whereas the distance b from the poles to the centre of the Earth is 6.36 Mm. The precise flattening $(a - b)/a$ has the value

Appendix C

$1/298.3 = 0.0034$. As a result, the top of Mount Chimborazo in Ecuador, even though its height is only 6267 m above sea level, is about 20 km farther away from the centre of the Earth than the top of Mount Sagarmatha* in Nepal, whose height above sea level is 8850 m. The top of Mount Chimborazo is in fact the point on the surface most distant from the centre of the Earth.

As a consequence, if the Earth stopped rotating (but kept its shape), the water of the oceans would flow north; all of Europe would be under water, except for the few mountains of the Alps that are higher than about 4 km. The northern parts of Europe would be covered by between 6 km and 10 km of water. Mount Sagarmatha would be over 11 km above sea level. If one takes into account the resulting change of shape of the Earth, the numbers come out smaller. In addition, the change in shape would produce extremely strong earthquakes and storms. As long as there are none of these effects, we can be *sure* that the Sun will indeed rise tomorrow, despite what some philosophers might pretend.

Page 133

Dynamics – how do things move in various dimensions?

Let us give a short summary. If a body can move only along a (possibly curved) line, the concepts of kinetic and potential energy are sufficient to determine the way it moves. In short, motion in *one dimension* follows directly from energy conservation.

* Mount Sagarmatha is sometimes also called Mount Everest.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

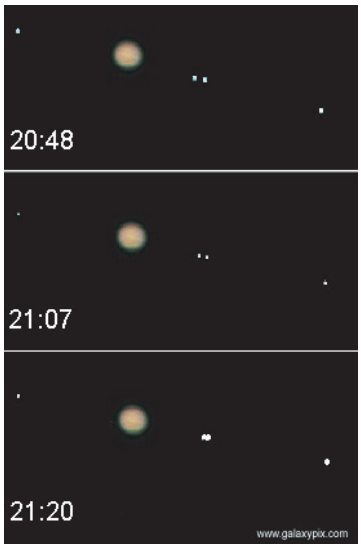

FIGURE 108 The four satellites of Jupiter discovered by Galileo and their motion (© Robin Scagell)

If more than *two spatial dimensions* are involved, energy conservation is insufficient to determine how a body moves. If a body can move in *two dimensions*, *and* if the forces involved are internal (which is always the case in theory, but not in practice), the conservation of angular momentum can be used. The full motion in two dimensions thus follows from energy and angular momentum conservation. For example, all properties of free fall follow from energy and angular momentum conservation. (Are you able to show this?) Challenge 273 s

In the case of motion in *three dimensions*, a more general rule for determining motion is necessary. It turns out that all motion follows from a simple principle: the time average of the difference between kinetic and potential energy must be as small as possible. This is called the *least action principle*. We will explain the details of this calculation method later. Page 194

For simple gravitational motions, motion is two-dimensional, in a plane. Most three-dimensional problems are outside the scope of this text; in fact, some of these problems are still subjects of research. In this adventure, we will explore three-dimensional motion only for selected cases that provide important insights.

Gravitation in the sky

The expression for the acceleration due to gravity $a = GM/r^2$ also describes the motion of all the planets around the Sun. Anyone can check that the planets always stay within the *zodiac*, a narrow stripe across the sky. The centre line of the zodiac gives the path of the Sun and is called the *ecliptic*, since the Moon must be located on it to produce an eclipse. But the detailed motion of the planets is not easy to describe.* A few generations before Hooke, the Swabian astronomer Johannes Kepler, in his painstaking research Page 176

* The apparent height of the ecliptic changes with the time of the year and is the reason for the changing seasons. Therefore seasons are a gravitational effect as well.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

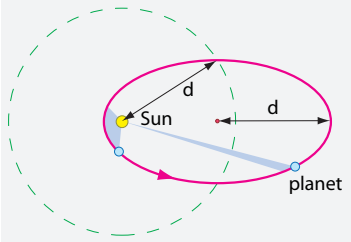

FIGURE 109 The motion of a planet around the Sun, showing its semimajor axis d, which is also the spatial average of its distance from the Sun

about the movements of the planets in the zodiac, had deduced several 'laws'. The three main ones are as follows:

1. Planets move on ellipses with the Sun located at one focus (1609).
2. Planets sweep out equal areas in equal times (1609).
3. All planets have the same ratio T^2/d^3 between the orbit duration T and the semimajor axis d (1619).

The results are illustrated in Figure 109. The sheer work required to deduce the three 'laws' was enormous. Kepler had no calculating machine available, not even a slide rule. The calculation technology he used was the recently discovered logarithms. Anyone who has used tables of logarithms to perform calculations can get a feeling for the amount of work behind these three discoveries.

The second 'law' about equal swept areas implies that planets move faster when they are near the Sun. It is a way to state the conservation of angular momentum. But now comes the central point. The huge volume of work by Brahe and Kepler can be summarized in the expression $a = GM/r^2$. Can you confirm that all three 'laws' follow from Challenge 274 s Hooke's expression of universal gravity? Publishing this result was the main achievement of Newton. Try to repeat his achievement; it will show you not only the difficulties, but also the possibilities of physics, and the joy that puzzles give.

Newton solved the puzzle with geometric drawing. Newton was not able to write down, let alone handle, differential equations at the time he published his results on Ref. 26 gravitation. In fact, it is well known that Newton's notation and calculation methods were poor. (Much poorer than yours!) The English mathematician Godfrey Hardy* used to say that the insistence on using Newton's integral and differential notation, rather than the earlier and better method, still common today, due to his rival Leibniz – threw back English mathematics by 100 years.

Kepler, Hooke and Newton became famous because they brought order to the description of planetary motion. This achievement, though of small practical significance, was widely publicized because of the age-old prejudices linked with astrology.

However, there is more to gravitation. Universal gravity explains the motion and shape of the Milky Way and of the other galaxies, the motion of many weather phenomena and explains why the Earth has an atmosphere but the Moon does not. (Can you

* Godfrey Harold Hardy (1877–1947) was an important English number theorist, and the author of the well-known *A Mathematician's Apology*. He also 'discovered' the famous Indian mathematician Srinivasa Ramanujan, bringing him to Britain.

FIGURE 110 The change of the moon during the month, showing its libration (QuickTime film © Martin Elsässer)

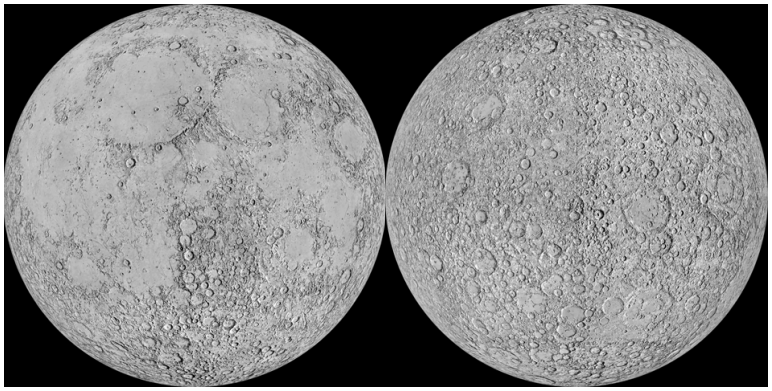

FIGURE 111 High resolution maps (not photographs) of the near side (left) and far side (right) of the moon, showing how often the latter saved the Earth from meteorite impacts (courtesy USGS)

Challenge 275 s explain this?) In fact, universal gravity explains much more about the Moon.

The Moon

How long is a day on the Moon? The answer is roughly 29 Earth-days. That is the time that it takes for an observer on the Moon to see the Sun again in the same position in the sky.

One often hears that the Moon always shows the same side to the Earth. But this is wrong. As one can check with the naked eye, a given feature in the centre of the face of the Moon at full Moon is not at the centre one week later. The various motions leading to this change are called *librations*; they are shown in the film in Figure 110. The motions appear mainly because the Moon does not describe a circular, but an elliptical orbit around the Earth and because the axis of the Moon is slightly inclined, compared with that of its rotation around the Earth. As a result, only around 45 % of the Moon's surface is permanently hidden from Earth.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The first photographs of the hidden area were taken in the 1960s by a Soviet artificial satellite; modern satellites provided exact maps, as shown in Figure 111. (Just zoom into the figure for fun.) The hidden surface is much more irregular than the visible one, as the hidden side is the one that intercepts most asteroids attracted by the Earth. Thus the gravitation of the Moon helps to deflect asteroids from the Earth. The number of animal life extinctions is thus reduced to a small, but not negligible number. In other words, the gravitational attraction of the Moon has saved the human race from extinction many times over.*

Challenge 276 e

The trips to the Moon in the 1970s also showed that the Moon originated from the Earth itself: long ago, an object hit the Earth almost tangentially and threw a sizeable fraction of material up into the sky. This is the only mechanism able to explain the large size of the Moon, its low iron content, as well as its general material composition.

Ref. 118

The Moon is receding from the Earth at 3.8 cm a year. This result confirms the old deduction that the tides slow down the Earth's rotation. Can you imagine how this measurement was performed? Since the Moon slows down the Earth, the Earth also changes shape due to this effect. (Remember that the shape of the Earth depends on its speed of rotation.) These changes in shape influence the tectonic activity of the Earth, and maybe also the drift of the continents.

Ref. 119

Challenge 277 s

The Moon has many effects on animal life. A famous example is the midge *Clunio*, which lives on coasts with pronounced tides. Clunio spends between six and twelve weeks as a larva, then hatches and lives for only one or two hours as an adult flying insect, during which time it reproduces. The midges will only reproduce if they hatch during the low tide phase of a spring tide. Spring tides are the especially strong tides during the full and new moons, when the solar and lunar effects combine, and occur only every 14.8 days. In 1995, Dietrich Neumann showed that the larvae have two built-in clocks, a circadian and a circalunar one, which together control the hatching to precisely those few hours when the insect can reproduce. He also showed that the circalunar clock is synchronized by the brightness of the Moon at night. In other words, the larvae monitor the Moon at night and then decide when to hatch: they are the smallest known astronomers.

Ref. 120

If insects can have circalunar cycles, it should come as no surprise that women also have such a cycle; however, in this case the precise origin of the cycle length is still unknown and a topic of research.

Ref. 121

The Moon also helps to stabilize the tilt of the Earth's axis, keeping it more or less fixed relative to the plane of motion around the Sun. Without the Moon, the axis would change its direction irregularly, we would not have a regular day and night rhythm, we would have extremely large climate changes, and the evolution of life would have been impossible. Without the Moon, the Earth would also rotate much faster and we would have much less clement weather. The Moon's main remaining effect on the Earth, the precession of its axis, is responsible for the ice ages.

Ref. 122

Ref. 123

Page 123

* The web pages cfa-www.harvard.edu/iau/lists/Closest.html and InnerPlot.html give an impression of the number of objects that almost hit the Earth every year. Without the Moon, we would have many additional catastrophes.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

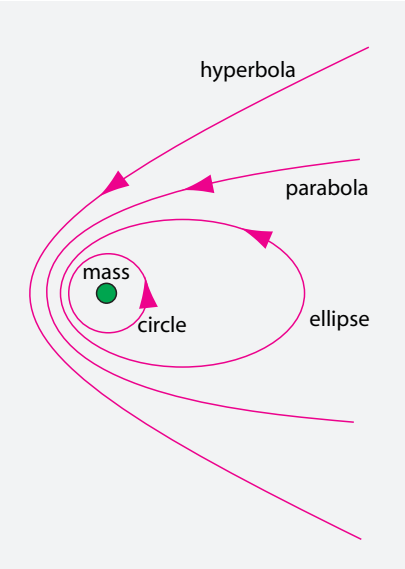

FIGURE 112 The possible orbits due to universal gravity around a large mass and a few examples of measured orbits

Orbits

The path of a body orbiting another under the influence of gravity is an ellipse with the central body at one focus. A circular orbit is also possible, a circle being a special case of an ellipse. Single encounters of two objects can also be parabolas or hyperbolas, as shown in Figure 112. Circles, ellipses, parabolas and hyperbolas are collectively known as *conic sections*. Indeed each of these curves can be produced by cutting a cone with a knife. Are you able to confirm this?

Challenge 278 e

If orbits are mostly ellipses, it follows that comets return. The English astronomer Edmund Halley (1656–1742) was the first to draw this conclusion and to predict the return of a comet. It arrived at the predicted date in 1756, and is now named after him. The period of Halley's comet is between 74 and 80 years; the first recorded sighting was 22 centuries ago, and it has been seen at every one of its 30 passages since, the last time in 1986.

Depending on the initial energy and the initial angular momentum of the body with respect to the central planet, there are two additional possibilities: *parabolic* paths and *hyperbolic* paths. Can you determine the conditions of the energy and the angular momentum needed for these paths to appear?

Challenge 279 ny

In practice, parabolic paths do not exist in nature. (Though some comets seem to approach this case when moving around the Sun; almost all comets follow elliptical paths). Hyperbolic paths do exist; artificial satellites follow them when they are shot towards a planet, usually with the aim of changing the direction of the satellite's journey across the solar system.

Why does the inverse square 'law' lead to conic sections? First, for two bodies, the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 113 The phases of the Moon and of Venus, as observed from Athens in summer 2007 (© Anthony Ayiomamitis)

total angular momentum L is a constant:

$$L = mr^2\dot{\varphi} \tag{41}$$

and therefore the motion lies in a plane. Also the energy E is a constant

$$E = \frac{1}{2}m\left(\frac{\mathrm{d}r}{\mathrm{d}t}\right)^2 + \frac{1}{2}m\left(r\frac{\mathrm{d}\varphi}{\mathrm{d}t}\right)^2 - G\frac{mM}{r} \,. \tag{42}$$

Challenge 280 ny Together, the two equations imply that

$$r = \frac{L^2}{Gm^2M}\,\frac{1}{1+\sqrt{1+\dfrac{2EL^2}{G^2m^3M^2}}\,\cos\varphi} \,. \tag{43}$$

Now, any curve defined by the general expression

$$r = \frac{C}{1+e\cos\varphi} \quad \text{or} \quad r = \frac{C}{1-e\cos\varphi} \tag{44}$$

is an ellipse for $0 < e < 1$, a parabola for $e = 1$ and a hyperbola for $e > 1$, one focus being at the origin. The quantity e, called the *eccentricity*, describes how squeezed the curve is. In other words, a body in orbit around a central mass follows a conic section.

In all orbits, also the heavy mass moves. In fact, both bodies orbit around the common centre of mass. Both bodies follow the same type of curve (ellipsis, parabola or hyperbola), but the sizes of the two curves differ.

Challenge 281 e

If more than two objects move under mutual gravitation, many additional possibilities for motions appear. The classification and the motions are quite complex. In fact, this so-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

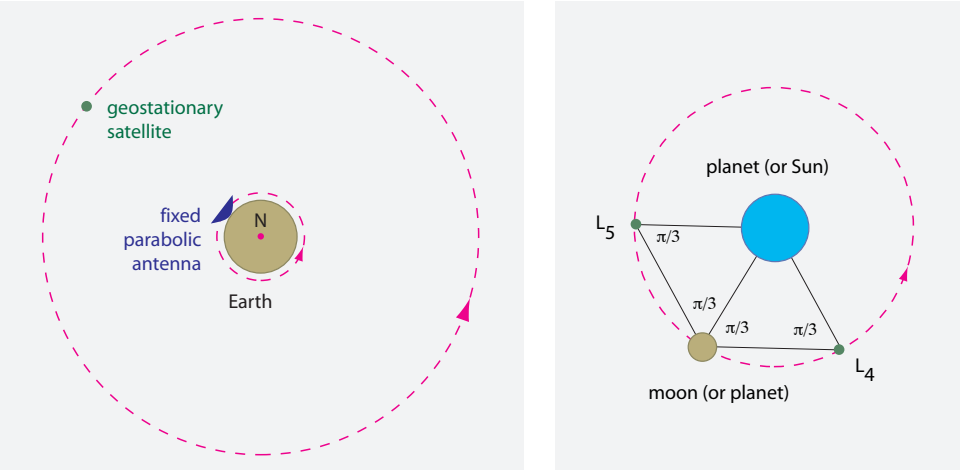

FIGURE 114 Geostationary satellites (left) and the main stable Lagrangian points (right)

called *many-body problem* is still a topic of research, and the results are mathematically fascinating. Let us look at a few examples.

When several planets circle a star, they also attract each other. Planets thus do not move in perfect ellipses. The largest deviation is a perihelion shift, as shown in Figure 90. It is observed for Mercury and a few other planets, including the Earth. Other deviations from elliptical paths appear during a single orbit. In 1846, the observed deviations of the motion of the planet Uranus from the path predicted by universal gravity were used to predict the existence of another planet, Neptune, which was discovered shortly afterwards.

Page 95 We have seen that mass is always positive and that gravitation is thus always attractive; there is no *antigravity*. Can gravity be used for *levitation* nevertheless, maybe using more than two bodies? Yes; there are two examples.* The first are the geostationary satellites, which are used for easy transmission of television and other signals from and towards Earth.

The *Lagrangian libration points* are the second example. Named after their discoverer, these are points in space near a two-body system, such as Moon–Earth or Earth–Sun, in which small objects have a stable equilibrium position. An overview is given in Figure 114.

Challenge 282 s Can you find their precise position, remembering to take rotation into account? There are three additional Lagrangian points on the Earth–Moon line (or Sun–planet line). How

Challenge 283 d many of them are stable?

There are thousands of asteroids, called *Trojan asteroids*, at and around the Lagrangian points of the Sun–Jupiter system. In 1990, a Trojan asteroid for the Mars–Sun system was discovered. Finally, in 1997, an 'almost Trojan' asteroid was found that follows the Earth on its way around the Sun (it is only transitionary and follows a somewhat more

Ref. 124 complex orbit). This 'second companion' of the Earth has a diameter of 5 km. Similarly, on the main Lagrangian points of the Earth–Moon system a high concentration of dust has been observed.

* Levitation is discussed in detail on page 782.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 115 Tides at Saint-Valéry en Caux on September 20, 2005 (© Gilles Régnier)

To sum up, the single equation $\boldsymbol{a} = -GM\boldsymbol{r}/r^3$ correctly describes a large number of phenomena in the sky. The first person to make clear that this expression describes *everything* happening in the sky was Pierre Simon Laplace* in his famous treatise *Traité de mécanique céleste*. When Napoleon told him that he found no mention about the creator in the book, Laplace gave a famous, one sentence summary of his book: *Je n'ai pas eu besoin de cette hypothèse.* 'I had no need for this hypothesis.' In particular, Laplace studied the stability of the solar system, the eccentricity of the lunar orbit, and the eccentricities of the planetary orbits, always getting full agreement between calculation and measurement.

These results are quite a feat for the simple expression of universal gravitation; they also explain why it is called 'universal'. But how precise is the formula? Since astronomy allows the most precise measurements of gravitational motion, it also provides the most stringent tests. In 1849, Urbain Le Verrier concluded after intensive study that there was only one known example of a discrepancy between observation and universal gravity, namely one observation for the planet Mercury. (Nowadays a few more are known.) The point of least distance to the Sun of the orbit of planet Mercury, its *perihelion*, changes at a rate that is slightly less than that predicted: he found a tiny difference, around 38″ per century. (This was corrected to 43″ per century in 1882 by Simon Newcomb.) Le Verrier thought that the difference was due to a planet between Mercury and the Sun, *Vulcan*, which he chased for many years without success. The study of motion had to wait for Albert Einstein to find the correct explanation of the difference.

Ref. 125

Tides

Ref. 126 Why do physics texts always talk about tides? Because, as general relativity will show,

* Pierre Simon Laplace (b. 1749 Beaumont-en-Auge, d. 1827 Paris), important French mathematician. His treatise appeared in five volumes between 1798 and 1825. He was the first to propose that the solar system was formed from a rotating gas cloud, and one of the first people to imagine and explore black holes.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

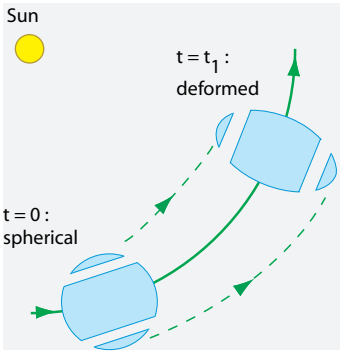

FIGURE 116 Tidal deformations due to gravity

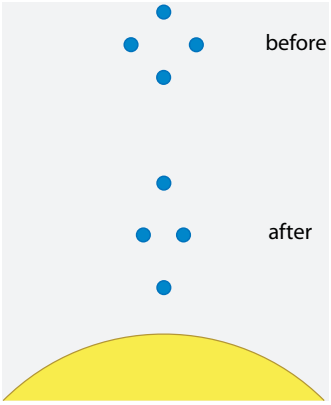

FIGURE 117 The origin of tides

tides prove that space is curved! It is thus useful to study them in a bit more detail. Gravitation explains the sea tides as results of the attraction of the ocean water by the Moon and the Sun. Tides are interesting; even though the amplitude of the tides is only about 0.5 m on the open sea, it can be up to 20 m at special places near the coast. Can you imagine why? The *soil* is also lifted and lowered by the Sun and the Moon, by about 0.3 m, as satellite measurements show. Even the *atmosphere* is subject to tides, and the corresponding pressure variations can be filtered out from the weather pressure measurements.

Challenge 284 s
Ref. 47
Ref. 127

Tides appear for any *extended* body moving in the gravitational field of another. To understand the origin of tides, picture a body in orbit, like the Earth, and imagine its components, such as the segments of Figure 116, as being held together by springs. Universal gravity implies that orbits are slower the more distant they are from a central body. As a result, the segment on the outside of the orbit would like to be slower than the central one; but it is *pulled* by the rest of the body through the springs. In contrast, the inside segment would like to orbit more rapidly but is *retained* by the others. Being slowed down, the inside segments want to fall towards the Sun. In sum, both segments feel a pull away from the centre of the body, limited by the springs that stop the deformation. Therefore, *extended bodies are deformed in the direction of the field inhomogeneity.*

For example, as a result of tidal forces, the Moon always has (roughly) the same face to the Earth. In addition, its radius in direction of the Earth is larger by about 5 m than the radius perpendicular to it. If the inner springs are too weak, the body is torn into pieces; in this way a *ring* of fragments can form, such as the asteroid ring between Mars and Jupiter or the rings around Saturn.

Let us return to the Earth. If a body is surrounded by water, it will form bulges in the direction of the applied gravitational field. In order to measure and compare the strength of the tides from the Sun and the Moon, we reduce tidal effects to their bare minimum. As shown in Figure 117, we can study the deformation of a body due to gravity by studying the deformation of four pieces. We can study it in free fall, because orbital motion and free fall are equivalent. Now, gravity makes some of the pieces approach and others diverge, depending on their relative positions. The figure makes clear that the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

strength of the deformation – water has no built-in springs – depends on the change of gravitational acceleration with distance; in other words, the *relative* acceleration that leads to the tides is proportional to the derivative of the gravitational acceleration.

Using the numbers from Appendix C, the gravitational accelerations from the Sun and the Moon measured on Earth are

$$a_{\text{Sun}} = \frac{GM_{\text{Sun}}}{d_{\text{Sun}}^2} = 5.9\,\text{mm/s}^2$$
$$a_{\text{Moon}} = \frac{GM_{\text{Moon}}}{d_{\text{Moon}}^2} = 0.033\,\text{mm/s}^2 \tag{45}$$

and thus the attraction from the Moon is about 178 times weaker than that from the Sun.

When two nearby bodies fall near a large mass, the relative acceleration is proportional to their distance, and follows $da = da/dr\, dr$. The proportionality factor $da/dr = \nabla a$, called the *tidal acceleration* (gradient), is the true measure of tidal effects. Near a large spherical mass M, it is given by

Challenge 285 e

$$\frac{da}{dr} = -\frac{2GM}{r^3} \tag{46}$$

which yields the values

$$\frac{da_{\text{Sun}}}{dr} = -\frac{2GM_{\text{Sun}}}{d_{\text{Sun}}^3} = -0.8 \cdot 10^{-13}\,/\text{s}^2$$
$$\frac{da_{\text{Moon}}}{dr} = -\frac{2GM_{\text{Moon}}}{d_{\text{Moon}}^3} = -1.7 \cdot 10^{-13}\,/\text{s}^2\ . \tag{47}$$

In other words, despite the much weaker pull of the Moon, its tides are predicted to be over *twice as strong* as the tides from the Sun; this is indeed observed. When Sun, Moon and Earth are aligned, the two tides add up; these so-called *spring tides* are especially strong and happen every 14.8 days, at full and new moon.

Tides lead to a pretty puzzle. Moon tides are much stronger than Sun tides. This implies that the Moon is much denser than the Sun. Why?

Challenge 286 s

Tides also produce *friction*. The friction leads to a slowing of the Earth's rotation. Nowadays, the slowdown can be measured by precise clocks (even though short time variations due to other effects, such as the weather, are often larger). The results fit well with fossil results showing that 400 million years ago, in the Devonian period, a year had 400 days, and a day about 22 hours. It is also estimated that 900 million years ago, each of the 481 days of a year were 18.2 hours long. The friction at the basis of this slowdown also results in an increase in the distance of the Moon from the Earth by about 3.8 cm per year. Are you able to explain why?

Ref. 90
Page 577
Challenge 287 s

As mentioned above, the tidal motion of the soil is also responsible for the triggering of *earthquakes*. Thus the Moon can have also dangerous effects on Earth. (Unfortunately, knowing the mechanism does not allow the prediction of earthquakes.) The most fascinating example of tidal effects is seen on Jupiter's satellite Io. Its tides are so strong that

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

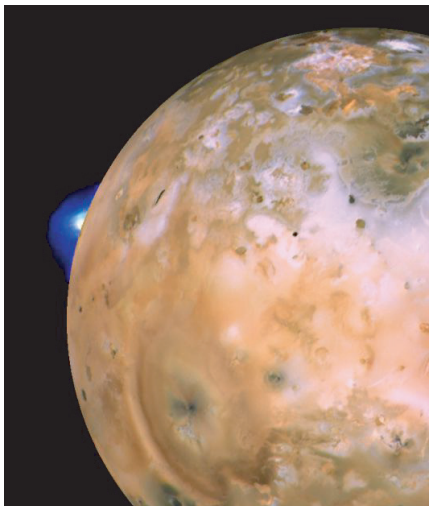

FIGURE 118 A spectacular result of tides: volcanism on Io (NASA)

they induce intense volcanic activity, as shown in Figure 118, with eruption plumes as high as 500 km. If tides are even stronger, they can destroy the body altogether, as happened to the body between Mars and Jupiter that formed the planetoids, or (possibly) to the moons that led to Saturn's rings.

In summary, tides are due to relative accelerations of nearby mass points. This has an important consequence. In the chapter on general relativity we will find that time multiplied by the speed of light plays the same role as length. Time then becomes an additional dimension, as shown in Figure 119. Using this similarity, two free particles moving in the same direction correspond to parallel lines in space-time. Two particles falling side-by-side also correspond to parallel lines. Tides show that such particles approach each other. In other words, tides imply that parallel lines approach each other. But parallel lines can approach each other *only* if space-time is curved. In short, tides imply *curved* space-time and space. This simple reasoning could have been performed in the eighteenth century; however, it took another 200 years and Albert Einstein's genius to uncover it.

Page 498
Page 544

Can light fall?

> Die Maxime, jederzeit selbst zu denken, ist die Aufklärung.
>
> Immanuel Kant*

Towards the end of the seventeenth century people discovered that light has a finite velocity – a story which we will tell in detail later. An entity that moves with infinite velocity cannot be affected by gravity, as there is no time to produce an effect. An entity with a finite speed, however, should feel gravity and thus fall.

Page 401

Does its speed increase when light reaches the surface of the Earth? For almost three centuries people had no means of detecting any such effect; so the question was not in-

* The maxim to think at all times for oneself is the enlightenment.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

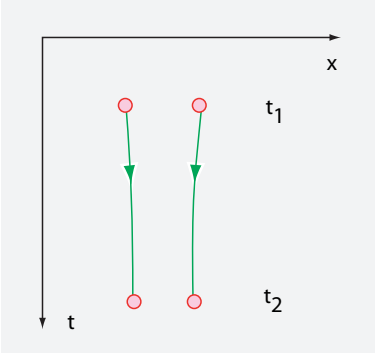

FIGURE 119 Particles falling side-by-side approach over time

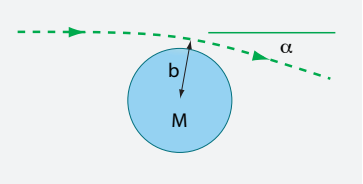

FIGURE 120 Masses bend light

vestigated. Then, in 1801, the Prussian astronomer Johann Soldner (1776–1833) was the Ref. 128 first to put the question in a different way. Being an astronomer, he was used to measuring stars and their observation angles. He realized that light passing near a massive body would be *deflected* due to gravity.

Soldner studied a body on a hyperbolic path, moving with velocity c past a spherical mass M at distance b (measured from the centre), as shown in Figure 120. Soldner Challenge 288 ny deduced the deflection angle

$$\alpha_{\text{univ. grav.}} = \frac{2}{b}\frac{GM}{c^2} \,. \tag{48}$$

One sees that the angle is largest when the motion is just grazing the mass M. For light deflected by the mass of the Sun, the angle turns out to be at most a tiny $0.88'' = 4.3\,\mu\text{rad}$. In Soldner's time, this angle was too small to be measured. Thus the issue was forgotten. Had it been pursued, general relativity would have begun as an experimental science, and Page 533 not as the theoretical effort of Albert Einstein! Why? The value just calculated is *different* from the measured value. The first measurement took place in 1919;* it found the correct dependence on the distance, but found a deflection of up to $1.75''$, exactly double that of expression (48). The reason is not easy to find; in fact, it is due to the curvature of space, as we will see. In summary, light can fall, but the issue hides some surprises.

What is mass? – Again

Mass describes how an object interacts with others. In our walk, we have encountered two of its aspects. *Inertial mass* is the property that keeps objects moving and that offers resistance to a change in their motion. *Gravitational mass* is the property responsible for the acceleration of bodies nearby (the active aspect) or of being accelerated by objects nearby (the passive aspect). For example, the active aspect of the mass of the Earth determines the surface acceleration of bodies; the passive aspect of the bodies allows us to weigh them in order to measure their mass using distances only, e.g. on a scale or a

Challenge 289 ny * By the way, how would you measure the deflection of light near the bright Sun?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

balance. The gravitational mass is the basis of *weight*, the difficulty of lifting things.*

Is the gravitational mass of a body equal to its inertial mass? A rough answer is given by the experience that an object that is difficult to move is also difficult to lift. The simplest experiment is to take two bodies of different masses and let them fall. If the acceleration is the same for all bodies, inertial mass is equal to (passive) gravitational mass, because in the relation $ma = \nabla(GMm/r)$ the left-hand m is actually the inertial mass, and the right-hand m is actually the gravitational mass.

But in the seventeenth century Galileo had made widely known an even older argument showing without a single experiment that the acceleration is indeed the same for all bodies. If larger masses fell more rapidly than smaller ones, then the following paradox would appear. Any body can be seen as being composed of a large fragment attached to a small fragment. If small bodies really fell less rapidly, the small fragment would slow the large fragment down, so that the complete body would have to fall *less* rapidly than the larger fragment (or break into pieces). At the same time, the body being larger than its fragment, it should fall *more* rapidly than that fragment. This is obviously impossible: all masses must fall with the same acceleration.

Many accurate experiments have been performed since Galileo's original discussion. In all of them the independence of the acceleration of free fall from mass and material composition has been confirmed with the precision they allowed. In other words, as far as we can tell, gravitational mass and inertial mass are *identical*. What is the origin of this mysterious equality?

Ref. 129

This so-called 'mystery' is a typical example of disinformation, now common across the whole world of physics education. Let us go back to the definition of mass as a negative inverse acceleration ratio. We mentioned that the physical origins of the accelerations do not play a role in the definition because the origin does not appear in the expression. In other words, the value of the mass is by definition independent of the interaction. That means in particular that inertial mass, based on electromagnetic interaction, and gravitational mass are identical *by definition*.

Page 91

We also note that we have never defined a separate concept of 'passive gravitational mass'. The mass being accelerated by gravitation is the inertial mass. Worse, there is no way to define a 'passive gravitational mass'. Try it! All methods, such as weighing an object, cannot be distinguished from those that determine inertial mass from its reaction to acceleration. Indeed, all methods of measuring mass use non-gravitational mechanisms. Scales are a good example.

Challenge 291 ny

If the 'passive gravitational mass' were different from the inertial mass, we would have strange consequences. For those bodies for which it were different we would get into trouble with energy conservation. Also assuming that 'active gravitational mass' differs from inertial mass gets us into trouble.

Another way of looking at the issue is as follows. How could 'gravitational mass' differ from inertial mass? Would the difference depend on relative velocity, time, position, composition or on mass itself? Each of these possibilities contradicts either energy or momentum conservation.

No wonder that all measurements confirm the equality of all mass types. The issue is usually resurrected in general relativity, with no new results. 'Both' masses remain equal;

Page 518

* What are the values shown by a balance for a person of 85 kg juggling three balls of 0.3 kg each?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

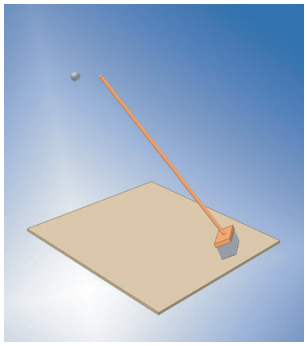

FIGURE 121 Brooms fall more rapidly than stones (© Luca Gastaldi)

mass is a unique property of bodies. Another issue remains, though. What is the *origin* of mass? Why does it exist? This simple but deep question cannot be answered by classical physics. We will need some patience to find out.

Curiosities and fun challenges about gravitation

> Fallen ist weder gefährlich noch eine Schande;
> Liegen bleiben ist beides.*
>

The *Galilean satellites* of Jupiter, shown in Figure 108 on page 151, can be seen with small amateur telescopes. Galileo discovered them in 1610 and called them the *Medicean satellites*. (Today, they are named, in order of increasing distance from Jupiter, as Io, Europa, Ganymede and Callisto.) They are almost mythical objects. They were the first bodies found that obviously did not orbit the Earth; thus Galileo used them to deduce that the Earth is not at the centre of the universe. The satellites have also been candidates to be the first *standard clock*, as their motion can be predicted to high accuracy, so that the 'standard time' could be read off from their position. Finally, due to this high accuracy, in 1676, the speed of light was first measured with their help, as told in the section on special relativity.

Page 402

* *

A simple, but difficult question: if all bodies attract each other, why don't or didn't all stars fall towards each other? Indeed, the inverse square expression of universal gravity has a limitation: it does not allow one to make sensible statements about the matter in the universe. Universal gravity predicts that a homogeneous mass distribution is unstable; indeed, an inhomogeneous distribution is observed. However, universal gravity does not predict the average mass density, the darkness at night, the observed speeds of the distant galaxies, etc. In fact, 'universal' gravity does not explain or predict a single property of the universe. To do this, we need general relativity.

Challenge 309 s

Page 564

FIGURE 127 The analemma over Delphi, between January and December 2002 (© Anthony Ayiomamitis)

* *

If you look at the sky every day at 6 a.m., the Sun's position varies during the year. The result of photographing the Sun on the same film is shown in Figure 127. The curve, called the analemma, is due to two combined effects: the inclination of the Earth's axis and the elliptical shape of the Earth's orbit around the Sun. The top and the (hidden) bottom points of the analemma correspond to the solstices. How does the analemma look if photographed every day at local noon? Why is it not a straight line pointing exactly south?

Challenge 317 s

* *

The constellation in which the Sun stands at noon (at the centre of the time zone) is supposedly called the 'zodiacal sign' of that day. Astrologers say there are twelve of them, namely Aries, Taurus, Gemini, Cancer, Leo, Virgo, Libra, Scorpius, Sagittarius, Capricornus, Aquarius and Pisces and that each takes (quite precisely) a twelfth of a year or a twelfth of the ecliptic. Any check with a calendar shows that at present, the midday Sun is never in the zodiacal sign during the days usually connected to it. The relation has shifted by about a month since it was defined, due to the precession of the Earth's axis. A check with a map of the star sky shows that the twelve constellations do not have the same length and that on the ecliptic there are fourteen of them, not twelve. There is *Ophiuchus*, the snake constellation, between Scorpius and Sagittarius, and *Cetus*, the whale, between Aquarius and Pisces. In fact, not a single astronomical statement about zodiacal signs is correct. To put it clearly, astrology, in contrast to its name, is *not* about stars. (In some languages, the term for 'crook' is derived from the word 'astrologer'.)

Page 129

Ref. 134

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

For a long time, it was thought that there is no additional planet in our solar system outside Neptune and Pluto, because their orbits show no disturbances from another body. Today, the view has changed. It is known that there are only eight planets: Pluto is not a planet, but the first of a set of smaller objects in the so-called Kuiper belt. Kuiper belt objects are regularly discovered; around 80 are known today.

Ref. 135

In 2003, two major Kuiper objects were discovered; one, called *Sedna*, is almost as large as Pluto, the other, called *Eris*, is even larger than Pluto and has a moon. Both have strongly elliptical orbits. (Since Pluto and Eris, like the asteroid Ceres, have cleaned their orbit from debris, these three objects are now classified as *dwarf planets*.)

Ref. 136

* *

In astronomy new examples of motion are regularly discovered even in the present century. Sometimes there are also false alarms. One example was the alleged fall of *mini comets* on the Earth. They were supposedly made of a few dozen kilograms of ice and hitting the Earth every few seconds. It is now known not to happen. On the other hand, it is known that many tons of asteroids fall on the Earth every day, in the form of tiny particles. Incidentally, discovering objects hitting the Earth is not at all easy. Astronomers like to point out that an asteroid as large as the one that led to the extinction of the dinosaurs could hit the Earth without any astronomer noticing in advance, if the direction is slightly unusual, such as from the south, where few telescopes are located.

Ref. 137

* *

Universal gravity allows only elliptical, parabolic or hyperbolic orbits. It is impossible for a small object approaching a large one to be captured. At least, that is what we have learned so far. Nevertheless, all astronomy books tell stories of capture in our solar system; for example, several outer satellites of Saturn have been captured. How is this possible?

Challenge 318 s

* *

How would a tunnel have to be shaped in order that a stone would fall through it without touching the walls? (Assume constant density.) If the Earth did not rotate, the tunnel would be a straight line through its centre, and the stone would fall down and up again, in a oscillating motion. For a rotating Earth, the problem is much more difficult. What is the shape when the tunnel starts at the Equator?

Challenge 319 s

* *

The International Space Station circles the Earth every 90 minutes at an altitude of about 380 km. You can see where it is from the website www.heavens-above.com. By the way, whenever it is just above the horizon, the station is the third brightest object in the night sky, superseded only by the Moon and Venus. Have a look at it.

Challenge 320 e

* *

Is it true that the centre of mass of the solar system, its barycentre, is always inside the Sun? Even though a star or the Sun move very little when planets move around them, this motion can be detected with precision measurements making use of the Doppler

Ref. 139 The gravitational acceleration for a particle inside a spherical shell is zero. The vanishing of gravity in this case is independent of the particle shape and its position, and independent of the thickness of the shell.Can you find the argument using Figure 128? This works only because of the $1/r^2$ dependence of gravity. Can you show that the result does not hold for non-spherical shells? Note that the vanishing of gravity inside a spherical shell usually does not hold if other matter is found outside the shell. How could one eliminate the effects of outside matter?

Challenge 327 s

Challenge 328 s

* *

What is gravity? This is not a simple question. In 1690, Nicolas Fatio de Duillier and in 1747, Georges-Louis Lesage proposed an explanation for the $1/r^2$ dependence. Lesage argued that the world is full of small particles – he called them 'corpuscules ultra-mondains' – flying around randomly and hitting all objects. Single objects do not feel the hits, since they are hit continuously and randomly from all directions. But when two objects are near to each other, they produce shadows for part of the flux to the other body, resulting in an attraction. Can you show that such an attraction has a $1/r^2$ dependence?

Ref. 140

Challenge 329 ny

However, Lesage's proposal has a number of problems. The argument only works if the collisions are inelastic. (Why?) However, that would mean that all bodies would heat up with time, as Jean-Marc Lévy-Leblond explains.

Ref. 2

There are two additional problems with the idea of Lesage. First, a moving body in free space would be hit by more or faster particles in the front than in the back; as a result, the body should be decelerated. Second, gravity would depend on size, but in a strange way. In particular, three bodies lying on a line should *not* produce shadows, as no such shadows are observed; but the naive model predicts such shadows.

Despite all the criticisms, this famous idea has regularly resurfaced in physics ever since, even though such particles have never been found. Only in the final part of our mountain ascent will we settle the issue.

If a star is made of high density material, the speed of a planet orbiting near to it could Challenge 335 s be greater than the speed of light. How does nature avoid this strange possibility?

* *

What will happen to the solar system in the future? This question is surprisingly hard to answer. The main expert of this topic, French planetary scientist Jacques Laskar, simu- Ref. 141 lated a few hundred million years of evolution using computer-aided calculus. He found Page 307 that the planetary orbits are stable, but that there is clear evidence of chaos in the evolution of the solar system, at a small level. The various planets influence each other in subtle and still poorly understood ways. Effects in the past are also being studied, such as the energy change of Jupiter due to its ejection of smaller asteroids from the solar system, or energy gains of Neptune. There is still a lot of research to be done in this field.

* *

One of the open problems of the solar system is the description of planet distances discovered in 1766 by Johann Daniel Titius (1729–1796) and publicized by Johann Elert Bode (1747–1826). Titius discovered that planetary distances d from the Sun can be approximated by

$$d = a + 2^n b \quad \text{with} \quad a = 0.4\,\text{AU}\,,\ b = 0.3\,\text{AU} \tag{51}$$

where distances are measured in astronomical units and n is the number of the planet. The resulting approximation is compared with observations in Table 25.

Interestingly, the last three planets, as well as the planetoids, were discovered *after* Bode's and Titius' deaths; the rule had successfully predicted Uranus' distance, as well as that of the planetoids. Despite these successes – and the failure for the last two planets – nobody has yet found a model for the formation of the planets that explains Titius' rule. The large satellites of Jupiter and of Uranus have regular spacing, but not according to the Titius–Bode rule.

Explaining or disproving the rule is one of the challenges that remains in classical Ref. 142 mechanics. Some researchers maintain that the rule is a consequence of scale invariance, Ref. 143 others maintain that it is a accident or even a red herring. The last interpretation is also suggested by the non-Titius–Bode behaviour of practically all extrasolar planets. The issue is not closed.

* *

Around 3000 years ago, the Babylonians had measured the orbital times of the seven celestial bodies. Ordered from longest to shortest, they wrote them down in Table 26.

The Babylonians also introduced the week and the division of the day into 24 hours. The Babylonians dedicated every one of the 168 hours of the week to a celestial body, following the order of Table 26. They also dedicated the whole day to that celestial body that

BODY	PERIOD
Saturn	29 a
Jupiter	12 a
Mars	687 d
Sun	365 d
Venus	224 d
Mercury	88 d
Moon	29 d

corresponds to the first hour of that day. The first day of the week was dedicated to Saturn; the present ordering of the other days of the week then follows from Table 26. This story was told by Cassius Dio (*c.* 160 to *c.* 230). Towards the end of Antiquity, the ordering was taken up by the Roman empire. In Germanic languages, including English, the Latin names of the celestial bodies were replaced by the corresponding Germanic gods. The order Saturday, Sunday, Monday, Tuesday, Wednesday, Thursday and Friday is thus a consequence of both the astronomical measurements and the astrological superstitions of the ancients.

The observed motion due to gravity can be shown to be the simplest possible, in the following sense. If we measure change of a falling object with $\int mv^2/2 - mgh\mathrm{d}t$, then a constant acceleration due to gravity *minimizes* the change in every example of fall. Can you confirm this?

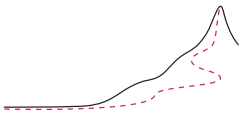
Page 198

Challenge 345 ny

Summary on gravitation

Spherical bodies of mass m attract others at a distance r by inducing an acceleration towards them given by $a = Gm/r^2$. This expression, *universal gravity*, describes snowboarders, skiers, paragliders, athletes, couch potatoes, pendula, stones, canons, rockets, tides, eclipses, planets and much more. It is the first example of a unified description, in this case, of *everything falling*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 7

CLASSICAL MECHANICS AND THE PREDICTABILITY OF MOTION

All those types of motion that can be described when the only permanent property of a body is mass, form the mass of a body is its only permanent property form what is called *mechanics*. The same name is also given to the experts studying the field. We can think of mechanics as the athletic part of physics;* both in athletics and in mechanics only lengths, times and masses are measured.

More specifically, our topic of investigation so far is called *classical* mechanics, to distinguish it from *quantum* mechanics. The main difference is that in classical physics arbitrary small values are assumed to exist, whereas this is not the case in quantum physics. Classical mechanics is often also called *Galilean physics* or *Newtonian physics*.**

Classical mechanics states that motion is *predictable*: it thus states that there are no surprises in motion. Is this correct in all cases? Let us start with the exploration of this issue.

We know that there is more to the world than gravity. A simple observation makes the point: *friction*. Friction cannot be due to gravity, because friction is not observed in the skies, where motion follows gravity rules only.*** Moreover, on Earth, friction is independent of gravity, as you might want to check. There must be another interaction responsible for friction. We shall study it shortly. But one issue merits a discussion right away.

Challenge 346 e

Should one use force? Power?

> The direct use of force is such a poor solution to any problem, it is generally employed only by small children and large nations.
>
> David Friedman

* This is in contrast to the actual origin of the term 'mechanics', which means 'machine science'. It derives from the Greek μηκανή, which means 'machine' and even lies at the origin of the English word 'machine' itself. Sometimes the term 'mechanics' is used for the study of motion of *solid* bodies only, excluding, e.g., hydrodynamics. This use fell out of favour in physics in the twentieth century.

** The basis of classical mechanics, the description of motion using only space and time, is called *kinematics*. An example is the description of free fall by $z(t) = z_0 + v_0(t - t_0) - \frac{1}{2}g(t - t_0)^2$. The other, main part of classical mechanics is the description of motion as a consequence of interactions between bodies; it is called *dynamics*. An example of dynamics is the formula of universal gravity. The distinction between kinematics and dynamics can also be made in relativity, thermodynamics and electrodynamics.

*** This is not completely correct: in the 1980s, the first case of gravitational friction was discovered: the emission of gravity waves. We discuss it in detail in the part on general relativity.

Page 525

TABLE 27 Some force values in nature

OBSERVATION	FORCE
Value measured in a magnetic resonance force microscope	820 zN
Force needed to rip a DNA molecule apart by pulling at its two ends	600 pN
Maximum force exerted by teeth	1.6 kN
Typical peak force exerted by sledgehammer	2 kN
Force exerted by quadriceps	up to 3 kN
Force sustained by $1\,\mathrm{cm}^2$ of a good adhesive	up to 10 kN
Force needed to tear a good rope used in rock climbing	30 kN
Maximum force measurable in nature	$3.0 \cdot 10^{43}$ N

Everybody has to take a stand on this question, even students of physics. Indeed, many types of forces are used and observed in daily life. One speaks of muscular, gravitational, psychic, sexual, satanic, supernatural, social, political, economic and many others. Physicists see things in a simpler way. They call the different types of forces observed between objects *interactions*. The study of the details of all these interactions will show that, in everyday life, they are of electrical origin.

For physicists, all change is due to motion. The term force then also takes on a more restrictive definition. *(Physical) force* is defined as the *change of momentum*, i.e., as

$$\boldsymbol{F} = \frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t} \,. \tag{52}$$

Force is the change or flow of momentum. If a force acts on a body, momentum flows into it. Indeed, momentum can be imagined to be some invisible and intangible liquid. Force measures how much of this liquid flows from one body to another per unit time.

Using the Galilean definition of linear momentum $\boldsymbol{p} = m\boldsymbol{v}$, we can rewrite the definition of force (for constant mass) as

$$\boldsymbol{F} = m\boldsymbol{a} \,, \tag{53}$$

where $\boldsymbol{F} = \boldsymbol{F}(t, \boldsymbol{x})$ is the force acting on an object of mass m and where $\boldsymbol{a} = \boldsymbol{a}(t, \boldsymbol{x}) = \mathrm{d}\boldsymbol{v}/\mathrm{d}t = \mathrm{d}^2\boldsymbol{x}/\mathrm{d}t^2$ is the acceleration of the same object, that is to say its change of velocity.* The expression states in precise terms that force is what changes the *velocity* of masses. The quantity is called 'force' because it corresponds in many, but *not* all aspects to muscular force. For example, the more force is used, the further a stone can be thrown.

However, whenever the concept of force is used, it should be remembered that *physical force is different from everyday force or everyday effort*. Effort is probably best approximated by the concept of *(physical) power*, usually abbreviated P, and defined (for constant

* This equation was first written down by the Swiss mathematician and physicist Leonhard Euler (1707–1783) in 1747, 20 years after the death of Newton, to whom it is usually and falsely ascribed. It was Euler, one of the greatest mathematicians of all time, not Newton, who first understood that this definition of force is useful in *every* case of motion, whatever the appearance, be it for point particles or extended objects, and be it rigid, deformable or fluid bodies. Surprisingly and in contrast to frequently-made statements, equation (53) is even correct in relativity, as shown on page 452.

Ref. 26

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

force) as

$$P = \frac{\mathrm{d}W}{\mathrm{d}t} = \boldsymbol{F} \cdot \boldsymbol{v} \tag{54}$$

in which *(physical) work* W is defined as $W = \boldsymbol{F} \cdot \boldsymbol{s}$. Physical work is a form of energy, as you might want to check. Work, as a form of energy, has to be taken into account when the conservation of energy is checked. Note that a man who walks carrying a heavy rucksack is hardly doing any work; why then does he get tired?

Challenge 347 s

Challenge 348 s

With the definition of work just given you can solve the following puzzles. What happens to the electricity consumption of an escalator if you walk on it instead of standing still? What is the effect of the definition of power for the salary of scientists?

Challenge 349 d

Ref. 146

When students in exams say that the force acting on a thrown stone is least at the highest point of the trajectory, it is customary to say that they are using an incorrect view, namely the so-called *Aristotelian view*, in which force is proportional to velocity. Sometimes it is even said that they are using a different concept of *state* of motion. Critics then add, with a tone of superiority, how wrong all this is. This is an example of intellectual disinformation. Every student knows from riding a bicycle, from throwing a stone or from pulling an object that increased effort results in increased speed. The student is right; those theoreticians who deduce that the student has a mistaken concept of *force* are wrong. In fact, instead of the *physical* concept of force, the student is just using the *everyday* version, namely effort. Indeed, the effort exerted by gravity on a flying stone is least at the highest point of the trajectory. Understanding the difference between physical force and everyday effort is the main hurdle in learning mechanics.*

Often the flow of momentum, equation (52), is not recognized as the definition of force. This is mainly due to an everyday observation: there seem to be forces without any associated acceleration or change in momentum, such as in a string under tension or in water at high pressure. When one pushes against a tree, there is no motion, yet a force is applied. If force is momentum flow, where does the momentum go? It flows into the slight deformations of the arms and the tree. In fact, when one starts pushing and thus deforming, the associated momentum change of the molecules, the atoms, or the electrons of the two bodies can be observed. After the deformation is established, and looking at even higher magnification, one can indeed find that a continuous and equal flow of momentum is going on in both directions. The nature of this flow will be clarified in the part on quantum theory.

As force is net momentum flow, it is only needed as a separate concept in everyday life, where it is useful in situations where net momentum flows are less than the total flows. At the microscopic level, momentum alone suffices for the description of motion. For example, the concept of *weight* describes the flow of momentum due to gravity. Thus we will hardly ever use the term 'weight' in the microscopic part of our adventure.

Before we can answer the question in the title, on the usefulness of force and power, we need more arguments. Through its definition, the concept of force is distinguished clearly from 'mass', 'momentum', 'energy' and 'power'. But where do forces originate? In

* This stepping stone is so high that many professional physicists do not really take it themselves; this is confirmed by the innumerable comments in papers that state that physical force is defined using mass, and, at the same time, that mass is defined using force (the latter part of the sentence being a fundamental mistake).

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

other words, which effects in nature have the capacity to accelerate bodies by pumping momentum into objects? Table 28 gives an overview.

Friction and motion

Every example of motion, from the one that lets us choose the direction of our gaze to the one that carries a butterfly through the landscape, can be put into one of the two leftmost columns of Table 28. Physically, the two columns are separated by the following criterion: in the first class, the acceleration of a body can be in a different direction from its velocity. The second class of examples produces only accelerations that are exactly *opposed* to the velocity of the moving body, as seen from the frame of reference of the braking medium. Such a resisting force is called *friction*, *drag* or a *damping*. All examples in the second class are types of friction. Just check.

Challenge 350 e

Friction can be so strong that all motion of a body against its environment is made impossible. This type of friction, called *static friction* or *sticking friction*, is common and important: without it, turning the wheels of bicycles, trains or cars would have no effect. Without static friction, wheels driven by a motor would have no grip. Similarly, not a single screw would stay tightened and no hair clip would work. We could neither run nor walk in a forest, as the soil would be more slippery than polished ice. In fact not only our own motion, but all *voluntary motion* of living beings is *based* on friction. The same is the case for self-moving machines. Without static friction, the propellers in ships, aeroplanes and helicopters would not have any effect and the wings of aeroplanes would produce no lift to keep them in the air. (Why?) In short, static friction is required whenever we or an engine want to move relative to our environment.

Challenge 351 s

Friction, sport, machines and predictability

Once an object moves through its environment, it is hindered by another type of friction; it is called *dynamic friction* and acts between bodies in relative motion. Without it, falling bodies would always rebound to the same height, without ever coming to a stop; neither parachutes nor brakes would work; worse, we would have no memory, as we will see later.*

Ref. 147

All motion examples in the second column of Table 28 include friction. In these examples, macroscopic energy is not conserved: the systems are *dissipative*. In the first column, macroscopic energy is constant: the systems are *conservative*.

The first two columns can also be distinguished using a more abstract, mathematical criterion: on the left are accelerations that can be derived from a potential, on the right, decelerations that can not. As in the case of gravitation, the description of any kind of motion is much simplified by the use of a potential: at every position in space, one needs only the single value of the potential to calculate the trajectory of an object, instead of the three values of the acceleration or the force. Moreover, the magnitude of the velocity of an object at any point can be calculated directly from energy conservation.

The processes from the second column *cannot* be described by a potential. These are

* Recent research suggest that maybe in certain crystalline systems, such as tungsten bodies on silicon, under ideal conditions gliding friction can be extremely small and possibly even vanish in certain directions of motion. This so-called *superlubrication* is presently a topic of research.

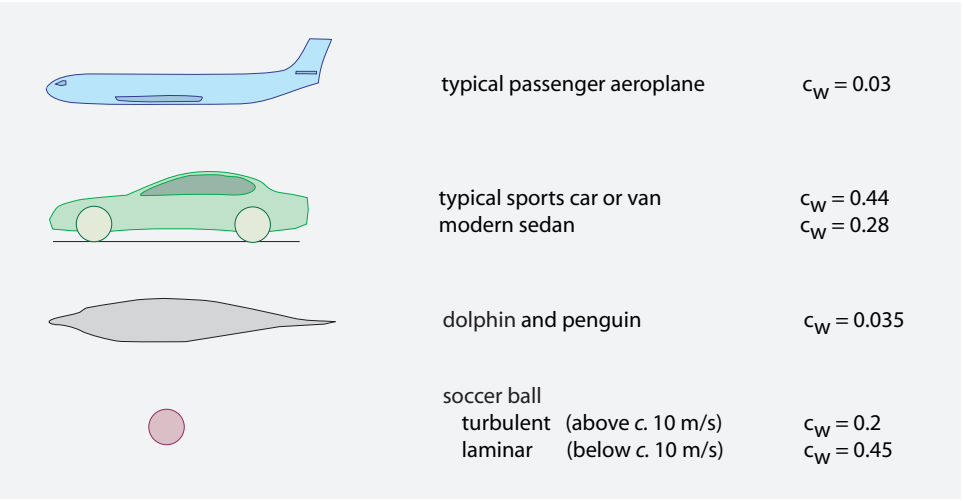

FIGURE 130 Shapes and air/water resistance

the cases where we necessarily have to use force if we want to describe the motion of the system. For example, the *friction* or *drag* force F due to wind resistance of a body is *roughly* given by

$$F = \frac{1}{2} c_w \rho A v^2 \tag{55}$$

where A is the area of its cross-section and v its velocity relative to the air, ρ is the density of air; the *drag coefficient* c_w is a pure number that depends on the shape of the moving object. (A few examples are given in Figure 130. The formula is valid for all fluids, not only for air, below the speed of sound, as long as the drag is due to turbulence. This is usually the case in air and in water. At low velocities, when the fluid motion is not turbulent but laminar, drag is called *viscous* and follows an (almost) linear relation with speed.) You may check that aerodynamic resistance cannot be derived from a potential.*

Challenge 352 ny

The drag coefficient c_w is a measured quantity.** An aerodynamic car has a value between 0.25 and 0.3; many sports cars share with vans values of 0.44 and higher, and racing car values can be as high as 1, depending on the amount of the force that is used to keep the car fastened to the ground. The lowest known values are for dolphins and penguins.

* Such a statement about friction is correct only in three dimensions, as is the case in nature; in the case of a single dimension, a potential can *always* be found.

Challenge 353 s

** Calculating drag coefficients in computers, given the shape of the body and the properties of the fluid, is one of the most difficult tasks of science; the problem is still not solved.

The topic of aerodynamic shapes is even more interesting for fluid bodies. They are kept together by *surface tension*. For example, surface tension keeps the hairs of a wet brush together. Surface tension also determines the shape of rain drops. Experiments show that it is spherical for drops smaller than 2 mm diameter, and that larger rain drops are *lens* shaped, with the flat part towards the bottom. The usual tear shape is *not* encountered in nature; something vaguely similar to it appears during drop detachment, but *never* during drop fall.

Page 1329
Ref. 149

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 150 Wind resistance is also of importance to humans, in particular in athletics. It is estimated that 100 m sprinters spend between 3 % and 6 % of their power overcoming drag. This leads to varying sprint times t_w when wind of speed w is involved, related by the expression

$$\frac{t_0}{t_w} = 1.03 - 0.03\left(1 - \frac{w\,t_w}{100\,\mathrm{m}}\right)^2 , \tag{56}$$

where the more conservative estimate of 3 % is used. An opposing wind speed of −2 m/s gives an increase in time of 0.13 s, enough to change a potential world record into an 'only' excellent result. (Are you able to deduce the c_w value for running humans from the formula?) Challenge 354 ny

Likewise, parachuting exists due to wind resistance. Can you determine how the speed of a falling body changes with time, assuming *constant* shape and drag coefficient? Challenge 355 s

In contrast, static friction has different properties. It is proportional to the force pressing the two bodies together. Why? Studying the situation in more detail, sticking friction is found to be proportional to the actual contact area. It turns out that putting two solids into contact is rather like turning Switzerland upside down and putting it onto Austria; the area of contact is much smaller than that estimated macroscopically. The important point is that the area of actual contact is proportional to the *normal* force. The study of what happens in that contact area is still a topic of research; researchers are investigating the issues using instruments such as atomic force microscopes, lateral force microscopes and triboscopes. These efforts resulted in computer hard discs which last longer, as the friction between disc and the reading head is a central quantity in determining the lifetime. Ref. 151

All forms of friction are accompanied by an increase in the temperature of the moving body. The reason became clear after the discovery of atoms. Friction is not observed in few – e.g. 2, 3, or 4 – particle systems. Friction only appears in systems with many particles, usually millions or more. Such systems are called *dissipative*. Both the temperature changes and friction itself are due to the motion of large numbers of microscopic particles against each other. This motion is not included in the Galilean description. When it is included, friction and energy loss disappear, and potentials can then be used throughout. Positive accelerations – of microscopic magnitude – then also appear, and motion is found to be conserved. As a result, all motion is conservative on a microscopic scale. Therefore, on a microscopic scale it is possible to describe *all* motion without the concept of force.*

The moral of the story is twofold: First, one should use force and power only in one situation: in the case of friction, and only when one does not want to go into the micro-

* The first scientist who eliminated force from the description of nature was Heinrich Rudolf Hertz (b. 1857 Hamburg, d. 1894 Bonn), the famous discoverer of electromagnetic waves, in his textbook on mechanics, *Die Prinzipien der Mechanik*, Barth, 1894, republished by Wissenschaftliche Buchgesellschaft, Darmstadt, 1963. His idea was strongly criticized at that time; only a generation later, when quantum mechanics quietly got rid of the concept for good, did the idea become commonly accepted. (Many have speculated about the role Hertz would have played in the development of quantum mechanics and general relativity, had he not died so young.) In his book, Hertz also formulated the principle of the straightest path: particles follow geodesics. This same description is one of the pillars of general relativity, as we will see later on.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

scopic details.* Secondly, friction is not an obstacle to predictability.

> Quid sit futurum cras, fuge quaerere ...***
>
> Horace, *Odi*, lib. I, ode 9, v. 13.

Let us continue our exploration of the predictability of motion. We often describe the motion of a body by specifying the time dependence of its position, for example as

$$\boldsymbol{x}(t) = \boldsymbol{x}_0 + \boldsymbol{v}_0(t - t_0) + \tfrac{1}{2}\boldsymbol{a}_0(t - t_0)^2 + \tfrac{1}{6}\boldsymbol{j}_0(t - t_0)^3 + \dots \,. \tag{57}$$

The quantities with an index 0, such as the starting position $\boldsymbol{x}_0$, the starting velocity $\boldsymbol{v}_0$, etc., are called *initial conditions*. Initial conditions are necessary for any description of motion. Different physical systems have different initial conditions. Initial conditions thus specify the *individuality* of a given system. Initial conditions also allow us to distinguish the present situation of a system from that at any previous time: initial conditions specify the *changing aspects* of a system. In other words, they summarize the past of a system.

Page 34 Initial conditions are thus precisely the properties we have been seeking for a description of the *state* of a system. To find a complete description of states we thus need only a complete description of initial conditions, which we can thus righty call also *initial states*. It turns out that for gravitation, as for all other microscopic interactions, there is *no* need for initial acceleration $\boldsymbol{a}_0$, initial jerk $\boldsymbol{j}_0$, or higher-order initial quantities. In nature, acceleration and jerk depend only on the properties of objects and their environment; they do not depend on the past. For example, the expression $a = GM/r^2$ of universal gravity, giving the acceleration of a small body near a large one, does not depend on the past, but only on the environment. The same happens for the other fundamental interactions, as we will find out shortly.

Page 83 The *complete state* of a moving mass point is thus described by specifying its position and its momentum at all instants of time. Thus we have achieved a complete description of the intrinsic properties of point objects, namely by their mass, and of their states of motion, namely by their momentum, energy, position and time. For *extended rigid* objects we also need orientation, angular velocity and angular momentum. Can you specify the necessary quantities in the cases of extended elastic bodies and of fluids? Challenge 356 ny

---

* In the case of human relations the evaluation should be somewhat more discerning, as the research by James Gilligan shows. Ref. 152

** 'And whatfor do we need this motor, when the reasoned study of nature proves to us that perpetual motion is the first of its laws?'

*** 'What future will be tomorrow, never ask ...' Horace is Quintus Horatius Flaccus (65–8 BCE), the great Roman poet. Ref. 68

The set of all possible states of a system is given a special name: it is called the *phase space*. We will use the concept repeatedly. Like any space, it has a number of dimensions. Challenge 357 s Can you specify it for a system consisting of N point particles?

Given that we have a description of both properties and states of point objects, extended rigid objects and deformable bodies, can we predict all motion? Not yet. There are situations in nature where the motion of an object depends on characteristics other Challenge 358 s than its mass; motion can depend on its colour (can you find an example?), on its temperature, and on a few other properties that we will soon discover. Can you give an example Challenge 359 s of an intrinsic property that we have so far missed? And for each intrinsic property there are state variables to discover. These new properties are the basis of the field of physical enquiry beyond mechanics. We must therefore conclude that as yet we do not have a complete description of motion.

It is interesting to recall an older challenge and ask again: does the universe have initial Challenge 360 s conditions? Does it have a phase space? As a hint, recall that when a stone is thrown, the initial conditions summarize the effects of the thrower, his history, the way he got there etc.; in other words, initial conditions summarize the effects that the environment had during the history of a system.

> Freedom is the recognition of necessity.
>
> Friedrich Engels (1820–1895)

If, after climbing a tree, we jump down, we cannot halt the jump in the middle of the trajectory; once the jump has begun, it is unavoidable and determined, like all passive motion. However, when we begin to move an arm, we can stop or change its motion from a hit to a caress. Voluntary motion does not seem unavoidable or predetermined. Which Challenge 361 e of these two cases is the general one?

Let us start with the example that we can describe most precisely so far: the fall of a body. Once the potential φ acting on a particle is given and taken into account, using

$$\boldsymbol{a}(x) = -\nabla\varphi = -GM\boldsymbol{r}/r^3 \,, \tag{58}$$

and once the state at a given time is given by initial conditions such as

$$\boldsymbol{x}(t_0) \quad \text{and} \quad \boldsymbol{v}(t_0) \,, \tag{59}$$

* 'We cannot infer the events of the future from those of the present. Belief in the causal nexus is superstition.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

we then can determine the motion of the particle in advance. The complete trajectory $\boldsymbol{x}(t)$ can be calculated with these two pieces of information.

An equation that has the potential to predict the course of events is called an *evolution equation*. Equation (58), for example, is an evolution equation for the motion of the object. (Note that the term 'evolution' has different meanings in physics and in biology.) An evolution equation embraces the observation that not all types of change are observed in nature, but only certain specific cases. Not all imaginable sequences of events are observed, but only a limited number of them. In particular, equation (58) embraces the idea that from one instant to the next, objects change their motion based on the potential acting on them. Given an evolution equation and initial state, the whole motion of a system is *uniquely fixed*, a property of motion often called *determinism*.

Let us carefully distinguish determinism from several similar concepts, to avoid misunderstandings. Motion can be deterministic and at the same time be *unpredictable in practice*. The unpredictability of motion can have four origins:

1. an impracticably large number of particles involved,
2. the mathematical complexity of the evolution equations,
3. insufficient information about initial conditions, and
4. strange shapes of space-time.

For example, in case of the weather the first three conditions are fulfilled at the same time. Nevertheless, weather change is still deterministic. As another example, near black holes all four origins apply together. We will discuss black holes in the section on general relativity. Despite being unpredictable, motion is deterministic near black holes.

Motion can be both deterministic and time *random*, i.e., with different outcomes in similar experiments. A roulette ball's motion is deterministic, but it is also random.* As we will see later, quantum-mechanical situations fall into this category, as do all examples of irreversible motion, such as a drop of ink spreading out in clear water. In all such cases the randomness and the irreproducibility are only apparent; they disappear when the description of states and initial conditions in the microscopic domain are included. In short, determinism does not contradict *(macroscopic) irreversibility*. However, on the microscopic scale, deterministic motion is always reversible.

A final concept to be distinguished from determinism is *acausality*. Causality is the requirement that a cause must precede the effect. This is trivial in Galilean physics, but becomes of importance in special relativity, where causality implies that the speed of light is a limit for the spreading of effects. Indeed, it seems impossible to have deterministic motion (of matter and energy) which is *acausal*, in other words, faster than light. Can you confirm this? This topic will be looked at more deeply in the section on special relativity. Challenge 362 s

Saying that motion is 'deterministic' means that it is fixed in the future *and also in the past*. It is sometimes stated that predictions of *future* observations are the crucial test for a successful description of nature. Owing to our often impressive ability to influence the future, this is not necessarily a good test. Any theory must, first of all, describe *past*

* Mathematicians have developed a large number of tests to determine whether a collection of numbers may be called *random*; roulette results pass all these tests – in honest casinos only, however. Such tests typically check the equal distribution of numbers, of pairs of numbers, of triples of numbers, etc. Other tests are the χ^2 test, the Monte Carlo test(s), and the gorilla test. Ref. 153

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

observations correctly. It is our lack of freedom to change the past that results in our lack of choice in the description of nature that is so central to physics. In this sense, the term 'initial condition' is an unfortunate choice, because it automatically leads us to search for the initial condition of the universe and to look there for answers to questions that can be answered without that knowledge. The central ingredient of a deterministic description is that all motion can be reduced to an evolution equation plus one specific state. This state can be either initial, intermediate, or final. Deterministic motion is uniquely specified into the past and into the future.

To get a clear concept of determinism, it is useful to remind ourselves why the concept of 'time' is introduced in our description of the world. We introduce time because we observe first that we are able to define sequences in observations, and second, that unrestricted change is impossible. This is in contrast to films, where one person can walk through a door and exit into another continent or another century. In nature we do not observe metamorphoses, such as people changing into toasters or dogs into toothbrushes. We are able to introduce 'time' only because the sequential changes we observe are extremely restricted. If nature were not reproducible, time could not be used. In short, determinism expresses the observation that *sequential changes are restricted to a single possibility*.

Challenge 363 s

Since determinism is connected to the use of the concept of time, new questions arise whenever the concept of time changes, as happens in special relativity, in general relativity and in theoretical high energy physics. There is a lot of fun ahead.

In summary, every description of nature that uses the concept of time, such as that of everyday life, that of classical physics and that of quantum mechanics, is intrinsically and inescapably deterministic, since it connects observations of the past and the future, *eliminating* alternatives. In short, *the use of time implies determinism, and vice versa.* When drawing metaphysical conclusions, as is so popular nowadays when discussing quantum theory, one should never forget this connection. Whoever uses clocks but denies determinism is nurturing a split personality![*]

Page 1138

Free will

> "You do have the ability to surprise yourself."
> Richard Bandler and John Grinder

The idea that motion is determined often produces fear, because we are taught to associate determinism with lack of freedom. On the other hand, we do experience freedom in our actions and call it *free will*. We know that it is necessary for our creativity and for our happiness. Therefore it seems that determinism is opposed to happiness.

But what precisely is free will? Much ink has been consumed trying to find a precise definition. One can try to define free will as the arbitrariness of the choice of initial conditions. However, initial conditions must themselves result from the evolution equations, so that there is in fact no freedom in their choice. One can try to define free will from the idea of unpredictability, or from similar properties, such as uncomputability. But these definitions face the same simple problem: whatever the definition, there is *no way* to prove experimentally that an action was performed freely. The possible definitions are

* That can be a lot of fun though.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

useless. In short, free will *cannot* be observed. (Psychologists also have a lot of their own data to support this, but that is another topic.)

No process that is *gradual* – in contrast to *sudden* – can be due to free will; gradual processes are described by time and are deterministic. In this sense, the question about free will becomes one about the existence of sudden changes in nature. This will be a recurring topic in the rest of this walk. Can nature surprise us? In everyday life, nature does not. Sudden changes are not observed. Of course, we still have to investigate this question in other domains, in the very small and in the very large. Indeed, we will change our opinion several times. The lack of surprises in everyday life is built deep into our body: the concept of curiosity is based on the idea that everything discovered is useful afterwards. If nature continually surprised us, curiosity would make no sense.

Many observations contradict the existence of surprises: in the beginning of our walk we defined time using the continuity of motion; later on we expressed this by saying that time is a consequence of the conservation of energy. Conservation is the opposite of surprise. By the way, a challenge remains: can you show that time would not be definable even if surprises existed only *rarely*?

Challenge 364 s

In summary, so far we have no evidence that surprises exist in nature. Time exists because nature is deterministic. Free will cannot be defined with the precision required by physics. Given that there are no sudden changes, there is only one consistent definition of free will: it is a *feeling*, in particular of independence of others, of independence from fear and of accepting the consequences of one's actions. Free will is a feeling of satisfaction. This solves the apparent paradox; free will, being a feeling, exists as a human experience, even though all objects move without any possibility of choice. There is no contradiction.*

Ref. 154

Even if human action is determined, it is still authentic. So why is determinism so frightening? That is a question everybody has to ask themselves. What difference does determinism imply for your life, for the actions, the choices, the responsibilities and the pleasures you encounter?** If you conclude that being determined is different from being free, you should change your life! Fear of determinism usually stems from refusal to take the world the way it is. Paradoxically, it is precisely he who insists on the existence of free will who is running away from responsibility.

Ref. 155

Challenge 366 e

Summary on predictability

Despite difficulties to predict specific cases, all motion we encountered so far is deterministic and predictable. In fact, this is the case for all motion in nature, even in the domain

* That free will is a feeling can also be confirmed by careful introspection. The idea of free will always appears *after* an action has been started. It is a beautiful experiment to sit down in a quiet environment, with the intention to make, within an unspecified number of minutes, a small gesture, such as closing a hand. If you carefully observe, in all detail, what happens inside yourself around the very moment of decision, you find either a mechanism that led to the decision, or a diffuse, unclear mist. You never find free will. Such an experiment is a beautiful way to experience deeply the wonders of the self. Experiences of this kind might also be one of the origins of human spirituality, as they show the connection everybody has with the rest of nature.

Challenge 365 e

** If nature's 'laws' are deterministic, are they in contrast with moral or ethical 'laws'? Can people still be held responsible for their actions?

Challenge 367 s

of quantum theory. If motion were not predictable, we could not have introduced the concept of 'motion' in the first place.

Global descriptions of motion

> Πλεῖν ἀνάγκε, ζῆν οὐκ ἀνάγκη.*
>
> Pompeius

All over the Earth – even in Australia – people observe that stones fall 'down'. This ancient observation led to the discovery of the universal 'law' of gravity. To find it, all that was necessary was to look for a description of gravity that was valid globally. The only additional observation that needs to be recognized in order to deduce the result $a = GM/r^2$ is the variation of gravity with height.

In short, thinking *globally* helps us to make our description of motion more precise and our predictions more useful. How can we describe motion as globally as possible? It turns out that there are six approaches to this question, each of which will be helpful on our way to the top of Motion Mountain. We first give an overview, and then explore the details of each approach.

1. *Variational principles*, the first global approach to motion, arises when we overcome a limitation of what we have learned so far. When we predict the motion of a particle from its current acceleration with an evolution equation, we are using the most *local* description of motion possible. We use the acceleration of a particle at a certain place and time to determine its position and motion *just after* that moment and *in the immediate neighbourhood* of that place. Evolution equations thus have a mental 'horizon' of radius zero.

Page 186

The contrast to evolution equations are variational principles. A famous example is illustrated in Figure 131. The challenge is to find the path that allows the fastest possible gliding motion from a high point to a distant low point. The sought path is the *brachistochrone*, from ancient Greek for 'shortest time'. This puzzle asks about a property of motion as a whole, for all times and positions. The global approach

Challenge 368 d

* Navigare necesse, vivere non necesse. 'To navigate is necessary, to live is not.' Gnaeus Pompeius Magnus (106–48 BCE) is cited in this way by Plutarchus (*c.* 45 to *c.* 125).

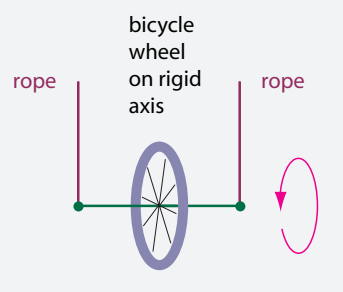

FIGURE 133 What happens when one rope is cut?

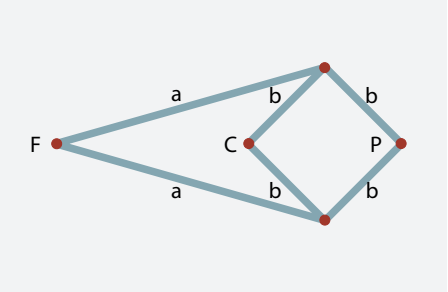

FIGURE 134 A famous mechanism that allows to draw a straight line with a compass: fix point F, put a pencil into joint P and move C with a compass along a circle

required by questions such as this one will lead us to a description of motion which is simple, precise and fascinating: the so-called principle of cosmic laziness, also known as the principle of least action.

2. *Relativity*, the second global approach to motion, emerges when we compare the various descriptions of the same system produced by different observers. For example, the observations by somebody falling from a cliff, a passenger in a roller coaster, and an observer on the ground will usually differ. The relationships between these observations lead us to a global description, valid for everybody. Later, this approach will lead us to Einstein's special theory of relativity.

3. *Mechanics of extended and rigid* bodies, rather than mass points, is required to understand many objects, plants and animals. As an example, the counter-intuitive result of the experiment in Figure 133 shows why this topic is worthwhile.

   In order to design machines, it is essential to understand how a group of rigid bodies interact with one another. For example, take the mechanism in Figure 134. A joint F is fixed on a wall. Two movable rods lead to two opposite corners of a movable rhombus, whose rods connect to the other two corners C and P. This mechanism has several astonishing properties. First of all, it implicitly defines a circle of radius R so that one always has the relation $r_C = R^2/r_P$ between the distances of joints C and P from the centre of this circle. Can you find this special circle? Secondly, if you put a pencil in joint P, and let joint C follow a certain circle, the pencil P draws a straight line. Can you find that circle? The mechanism thus allows to draw a straight line with a compass.

Challenge 369 ny

Challenge 370 ny

Ref. 157

Another famous machine challenge is to devise a wooden carriage, with gearwheels that connect the wheels to an arrow, with the property that, whatever path the carriage takes, the arrow always points south (see Figure 135). The solution to this puzzle will even be useful in helping us to understand general relativity, as we will see. Such a wagon allows to measure the curvature of a surface and of space.

Challenge 371 d

Page 561

Another interesting example of rigid motion is the way that human movements, such as the general motions of an arm, are composed from a small number of basic motions. All these examples are from the fascinating field of engineering; unfortu-

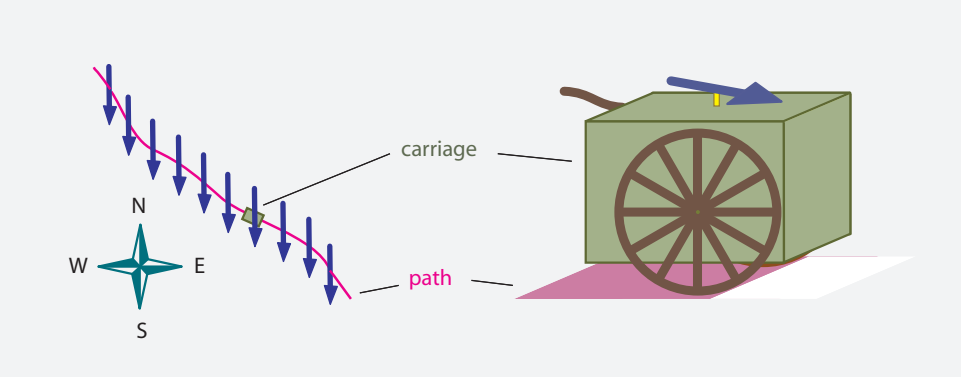

FIGURE 135 A south-pointing carriage: whatever the path it follows, the arrow on it always points south

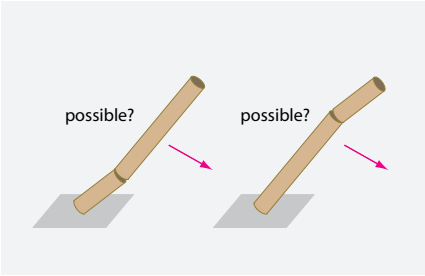

FIGURE 136 How and where does a falling brick chimney break?

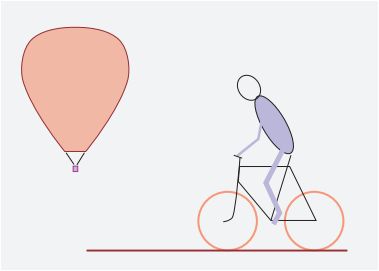

FIGURE 137 Why do hot-air balloons stay inflated? How can you measure the weight of a bicycle rider using only a ruler?

nately, we will have little time to explore this topic in our hike.

4. The next global approach to motion is the description of *non-rigid extended bodies*. For example, *fluid mechanics* studies the flow of fluids (like honey, water or air) around solid bodies (like spoons, ships, sails or wings). Fluid mechanics thus describes how insects, birds and aeroplanes fly,* why sailing-boats can sail against the wind, what happens when a hard-boiled egg is made to spin on a thin layer of water, or how a bottle full of wine can be emptied in the fastest way possible.

Ref. 159

Challenge 372 s

As well as fluids, we can study the behaviour of deformable *solids*. This area of research is called *continuum mechanics*. It deals with deformations and oscillations of extended structures. It seeks to explain, for example, why bells are made in particular shapes; how large bodies – such as falling chimneys – or small bodies – such as dia-

Challenge 373 s

* The mechanisms of insect flight are still a subject of active research. Traditionally, fluid dynamics has concentrated on large systems, like boats, ships and aeroplanes. Indeed, the smallest human-made object that can fly in a controlled way – say, a radio-controlled plane or helicopter – is much larger and heavier than many flying objects that evolution has engineered. It turns out that controlling the flight of small things requires more knowledge and more tricks than controlling the flight of large things. There is more about this topic on page 1303.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 138 Why do marguerites – or ox-eye daisies, *Leucanthemum vulgare* – usually have around 21 (left and centre) or around 34 (right) petals? (© Anonymous, Giorgio Di Iorio and Thomas Lüthi)

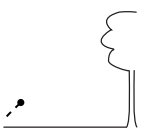
monds – break when under stress; and how cats can turn themselves the right way up as they fall. During the course of our journey we will repeatedly encounter issues from this field, which impinges even upon general relativity and the world of elementary particles.

5. *Statistical mechanics* is the study of the motion of huge numbers of particles. Statistical mechanics is yet another global approach to the study of motion. The concepts needed to describe gases, such as temperature, entropy and pressure (see Figure 137), are essential tools of this discipline. These concepts will also help us take our first steps towards the understanding of black holes.

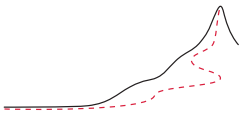
6. The last global approach to motion, *self-organization*, involves all of the above-mentioned viewpoints *at the same time*. Such an approach is needed to understand everyday experience, and *life* itself. Why does a flower form a specific number of petals? How does an embryo differentiate in the womb? What makes our hearts beat? How do mountains ridges and cloud patterns emerge? How do stars and galaxies evolve? How are sea waves formed by the wind?

   All these are examples of *self-organization* processes; life scientists simply speak of *growth* processes. Whatever we call them, all these processes are characterized by the spontaneous appearance of patterns, shapes and cycles. Such processes are a common research theme across many disciplines, including biology, chemistry, medicine, geology and engineering.

We will now explore to these six global approaches to motion. We will begin with the first approach, namely, the global description of moving point-like objects with a variational principle. This beautiful method was the result of several centuries of collective effort, and is the highlight of point particle dynamics. It also provides the basis for the other global approaches and for all the further descriptions of motion that we will explore afterwards.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 8

MEASURING CHANGE WITH ACTION

Motion can be described by numbers. For a single particle, the relations between the spatial and temporal coordinates describe the motion. The realization that expressions like $(x(t), y(t), z(t))$ could be used to describe the path of a moving particle was a milestone in the development of modern physics.

We can go further. Motion is a type of *change*. And this change can itself be usefully described by numbers. In fact, change can be measured by a single number. This realization was the next important milestone. Physicists took almost two centuries of attempts to uncover the way to describe change. As a result, the quantity that measures change has a strange name: it is called *(physical) action*.* To remember the connection of 'action' with change, just think about a Hollywood film: a lot of action means a large amount of change.

Imagine taking two snapshots of a system at different times. How could you define the amount of change that occurred in between? When do things change a lot, and when do they change only a little? First of all, a system with many moving parts shows a lot of change. So it makes sense that the action of a system composed of independent subsystems should be the sum of the actions of these subsystems. And systems with large speeds, such as the explosions shown in Figure 140, show larger change than systems at lower speed.

Secondly, change often – but not always – builds up over time; in other cases, recent change can compensate for previous change, as in a pendulum. Change can thus increase or decrease with time.

Thirdly, for a system in which motion is stored, transformed or shifted from one subsystem to another, especially when kinetic energy is stored or changed to potential energy,

* Note that this 'action' is not the same as the 'action' appearing in statements such as 'every action has an equal and opposite reaction'. This last usage, coined by Newton for certain forces, has not stuck; therefore the term has been recycled. After Newton, the term 'action' was first used with an intermediate meaning, before it was finally given the modern meaning used here. This last meaning is the only meaning used in this text.

Another term that has been recycled is the 'principle of least action'. In old books it used to have a different meaning from the one in this chapter. Nowadays, it refers to what used to be called *Hamilton's principle* in the Anglo-Saxon world, even though it is (mostly) due to others, especially Leibniz. The old names and meanings are falling into disuse and are not continued here.

Behind these shifts in terminology is the story of an intense two-centuries-long attempt to describe motion with so-called *extremal* or *variational principles*: the objective was to complete and improve the work initiated by Leibniz. These principles are only of historical interest today, because all are special cases of the principle of least action described here. Ref. 160

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 139 Giuseppe/Joseph Lagrangia/Lagrange

FIGURE 140 Physical action measures change: an example of process with large action value (© Christophe Blanc)

change is smaller than for a system where all systems move freely.

The mentioned properties imply that the natural measure of change is the average difference between kinetic and potential energy multiplied by the elapsed time. This quantity has all the right properties: it is the sum of the corresponding quantities for all subsystems if these are independent; it generally increases with time (unless the evolution compensates for something that happened earlier); and it decreases if the system transforms motion into potential energy.

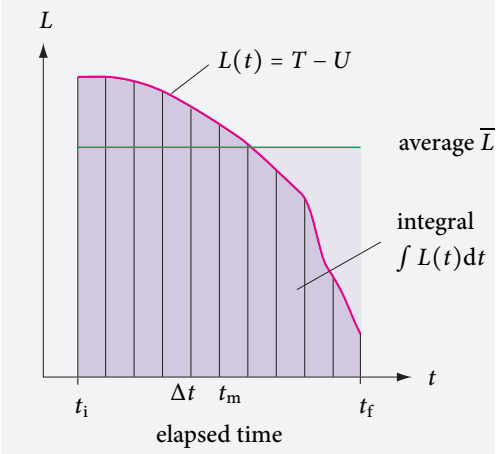

FIGURE 141 Defining a total change or action as an accumulation (addition, or integral) of small changes or actions over time

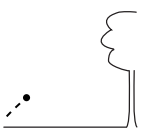
Thus the (physical) *action* S, measuring the change in a system, is defined as

$$S = \overline{L} \cdot (t_f - t_i) = \overline{T - U} \cdot (t_f - t_i) = \int_{t_i}^{t_f} (T - U)\, \mathrm{d}t = \int_{t_i}^{t_f} L\, \mathrm{d}t\,, \qquad (60)$$



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Page 148 where T is the kinetic energy, U the potential energy we already know, L is the difference between these, and the overbar indicates a time average. The quantity L is called the *Lagrangian (function)* of the system,* describes what is being added over time, whenever things change. The sign $\int$ is a stretched 'S', for 'sum', and is pronounced 'integral of'. In intuitive terms it designates the operation (called *integration*) of adding up the values of a varying quantity in infinitesimal time steps $\mathrm{d}t$. The initial and the final times are written below and above the integration sign, respectively. Figure 141 illustrates the idea: the integral is simply the size of the dark area below the curve $L(t)$.

Challenge 375 e Mathematically, the integral of the curve $L(t)$ is defined as

$$\int_{t_\mathrm{i}}^{t_\mathrm{f}} L(t)\,\mathrm{d}t = \lim_{\Delta t \to 0} \sum_{\mathrm{m=i}}^{\mathrm{f}} L(t_\mathrm{m})\Delta t = \overline{L} \cdot (t_\mathrm{f} - t_\mathrm{i}) \,. \tag{61}$$

In other words, the integral is the limit, as the time slices get smaller, of the sum of the areas of the individual rectangular strips that approximate the function.** Since the $\sum$ sign also means a sum, and since an infinitesimal Δt is written $\mathrm{d}t$, we can understand the notation used for integration. Integration is a sum over slices. The notation was developed by Gottfried Leibniz to make exactly this point. Physically speaking, the integral of the Lagrangian measures the *effect* that L builds up over time. Indeed, action is called 'effect' in some languages, such as German.

In short, then, action is the integral of the Lagrangian over time. The unit of action, and thus of physical change, is the unit of energy (the Joule) times the unit of time (the second). Thus change is measured in Js. A large value means a big change. Table 29 shows some values of actions.

To understand the definition of action in more detail, we will start with the simplest case: a system for which the potential energy is zero, such as a particle moving freely. Obviously, the higher the kinetic energy is, the more change there is. Also, if we observe the particle at two instants, the more distant they are the larger the change. This is not surprising.

Next, we explore a single particle moving in a potential. For example, a falling stone loses potential energy in exchange for a gain in kinetic energy. The more energy is exchanged, the more change there is. Hence the minus sign in the definition of L. If we explore a particle that is first thrown up in the air and then falls, the curve for $L(t)$ first is below the times axis, then above. We note that the definition of integration makes us count the grey surface *below* the time axis *negatively*. Change can thus be negative, and be compensated by subsequent change, as expected.

To measure change for a system made of several independent components, we simply add all the kinetic energies and subtract all the potential energies. This technique allows

* It is named after Giuseppe Lodovico Lagrangia (b. 1736 Torino, d. 1813 Paris), better known as Joseph Louis Lagrange. He was the most important mathematician of his time; he started his career in Turin, then worked for 20 years in Berlin, and finally for 26 years in Paris. Among other things he worked on number theory and analytical mechanics, where he developed most of the mathematical tools used nowadays for calculations in classical mechanics and classical gravitation. He applied them successfully to many motions in the solar system.

** For more details on integration see Appendix B.

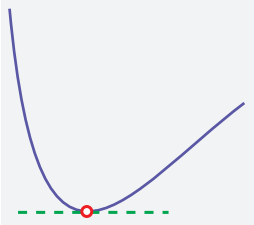

FIGURE 142 The minimum of a curve has vanishing slope

us to define actions for gases, liquids and solid matter. Even if the components interact, we still get a sensible result. In short, action is an *additive* quantity.

Physical action thus measures, in a single number, the change observed in a system between two instants of time. The observation may be anything at all: an explosion, a caress or a colour change. We will discover later that describing change with a single number is also possible in relativity and quantum theory. Any change going on in any system of nature can be measured with a single number.

The principle of least action

We now have a precise measure of change, which, as it turns out, allows a simple and powerful description of motion. In nature, the change happening between two instants is always the *smallest* possible. *In nature, action is minimal.** Of all possible motions, nature always chooses for which the change is *minimal*. Let us study a few examples.

In the simple case of a free particle, when no potentials are involved, the principle of minimal action implies that the particle moves in a *straight* line with *constant* velocity.

Challenge 376 e All other paths would lead to larger actions. Can you verify this?

When gravity is present, a thrown stone flies along a parabola (or more precisely, along an ellipse) because any other path, say one in which the stone makes a loop in the air,

Challenge 377 e would imply a *larger* action. Again you might want to verify this for yourself.

All observations support this simple and basic statement: things always move in a way that produces the smallest possible value for the action. This statement applies to the full path and to any of its segments. Betrand Russell called it the 'law of cosmic laziness'.

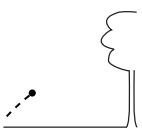
It is customary to express the idea of minimal change in a different way. The action varies when the path is varied. The actual path is the one with the smallest action. You will recall from school that at a minimum the derivative of a quantity vanishes: a minimum has a horizontal slope. In the present case, we do not vary a quantity, but a complete path; hence we do not speak of a derivative or slope, but of a variation. It is customary to write the variation of action as δS. The *principle of least action* thus states:

$$\triangleright \textit{ The actual trajectory between specified end points satisfies } \delta S = 0. \qquad (62)$$

Mathematicians call this a *variational principle*. Note that the end points have to be spec-

* In fact, in some macroscopic situations the action can be a saddle point, so that the snobbish form of the

Ref. 161 principle is that the action is 'stationary'. In contrast to what is often heard, the action is *never* a maximum. Moreover, for motion on small (infinitesimal) scales, the action is always a minimum. The mathematical condition of vanishing variation, given below, encompasses all these details.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ified: we have to compare motions with the *same* initial and final situations.

Before discussing the principle further, we can check that it is equivalent to the evolution equation.* To do this, we can use a standard procedure, part of the so-called *calculus of variations*. The condition $\delta S = 0$ implies that the action, i.e., the area under the curve in Figure 141, is a minimum. A little bit of thinking shows that if the Lagrangian is of the form $L(x_n, v_n) = T(v_n) - U(x_n)$, then

Challenge 379 ny

---

* For those interested, here are a few comments on the equivalence of Lagrangians and evolution equations. First of all, Lagrangians do not exist for non-conservative, or *dissipative* systems. We saw that there is no potential for any motion involving *friction* (and more than one dimension); therefore there is no action in these cases. One approach to overcome this limitation is to use a generalized formulation of the principle of least action. Whenever there is no potential, we can express the *work* variation δW between different trajectories x_i as

Page 181

$$\delta W = \sum_i m_i \ddot{x}_i \delta x_i \,. \tag{63}$$

Motion is then described in the following way:

$$\triangleright \textit{ The actual trajectory satifies } \int_{t_i}^{t_f} (\delta T + \delta W) \mathrm{d}t = 0 \quad \textit{provided} \quad \delta x(t_i) = \delta x(t_f) = 0 \,. \tag{64}$$

The quantity being varied has no name; it represents a generalized notion of change. You might want to check that it leads to the correct evolution equations. Thus, although *proper* Lagrangian descriptions exist only for *conservative* systems, for dissipative systems the principle can be generalized and remains useful.

Challenge 378 ny

Many physicists will prefer another approach. What a mathematician calls a generalization is a special case for a physicist: the principle (64) hides the fact that *all* friction results from the usual principle of minimal action, if we include the complete microscopic details. There is no friction in the microscopic domain. Friction is an approximate, macroscopic concept.

Nevertheless, more mathematical viewpoints are useful. For example, they lead to interesting limitations for the use of Lagrangians. These limitations, which apply only if the world is viewed as purely classical – which it isn't – were discovered about a hundred years ago. In those times computers where not available, and the exploration of new calculation techniques was important. Here is a summary.

The coordinates used in connection with Lagrangians are not necessarily the Cartesian ones. *Generalized* coordinates are especially useful when there are *constraints* on the motion. This is the case for a pendulum, where the weight always has to be at the same distance from the suspension, or for an ice skater, where the skate has to move in the direction in which it is pointing. Generalized coordinates may even be mixtures of positions and momenta. They can be divided into a few general types.

Ref. 162

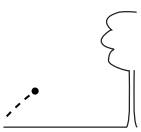
Generalized coordinates are called *holonomic–scleronomic* if they are related to Cartesian coordinates in a fixed way, independently of time: physical systems described by such coordinates include the pendulum and a particle in a potential. Coordinates are called *holonomic–rheonomic* if the dependence involves time. An example of a rheonomic systems would be a pendulum whose length depends on time. The two terms rheonomic and scleronomic are due to Ludwig Boltzmann. These two cases, which concern systems that are only described by their geometry, are grouped together as *holonomic systems*. The term is due to Heinrich Hertz.

Page 287

Page 724

The more general situation is called *anholonomic*, or *nonholonomic*. Lagrangians work well only for holonomic systems. Unfortunately, the meaning of the term 'nonholonomic' has changed. Nowadays, the term is also used for certain rheonomic systems. The modern use calls nonholonomic any system which involves velocities. Therefore, an ice skater or a rolling disc is often called a nonholonomic system. Care is thus necessary to decide what is meant by nonholonomic in any particular context.

Even though the use of Lagrangians, and of action, has its limitations, these need not bother us at microscopic level, since microscopic systems are always conservative, holonomic and scleronomic. At the fundamental level, evolution equations and Lagrangians are indeed equivalent.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial T}{\partial v_\mathrm{n}}\right) = -\frac{\partial U}{\partial x_\mathrm{n}} \tag{65}$$

where n counts all coordinates of all particles.* For a single particle, these *Lagrange's equations of motion* reduce to

Challenge 380 e

$$m\boldsymbol{a} = -\nabla U \,. \tag{67}$$

This is the evolution equation: it says that the force acting on a particle is the gradient of the potential energy U. The principle of least action thus implies the equation of motion. (Can you show the converse, which is also correct?)

Challenge 381 s

In other words, *all systems evolve in such a way that the change or action is as small as possible.* Nature is economical. Nature is thus the opposite of a Hollywood thriller, in which the action is maximized; nature is more like a wise old man who keeps his actions to a minimum.

The principle of minimal action states that the actual trajectory is the one for which the *average* of the Lagrangian over the whole trajectory is minimal (see Figure 141). Nature is a Dr. Dolittle. Can you verify this? This viewpoint allows one to deduce Lagrange's equations (65) directly.

Challenge 382 ny

The principle of least action distinguishes the actual trajectory from all other imaginable ones. This observation lead Leibniz to his famous interpretation that the actual world is the 'best of all possible worlds.'** We may dismiss this as metaphysical speculation, but we should still be able to feel the fascination of the issue. Leibniz was so excited about the principle of least action because it was the first time that actual observations were distinguished from all other imaginable possibilities. For the first time, the search for reasons why things are the way they are became a part of physical investigation. Could the world be different from what it is? In the principle of least action, we have a hint of a negative answer. (What do you think?) The final answer will emerge only in the last part of our adventure.

Challenge 383 s

Lagrangians and motion

> Never confuse movement with action.
> Ernest Hemingway

Ref. 165

* The most general form for a Lagrangian $L(q_\mathrm{n}, \dot{q}_\mathrm{n}, t)$, using generalized holonomic coordinates q_n, leads to Lagrange equations of the form

$$\frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{\partial L}{\partial \dot{q}_\mathrm{n}}\right) = \frac{\partial L}{\partial q_\mathrm{n}} \,. \tag{66}$$

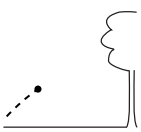
In order to deduce these equations, we also need the relation $\delta\dot{q} = \mathrm{d}/\mathrm{d}t(\delta q)$. This relation is valid only for *holonomic* coordinates introduced in the previous footnote and explains their importance.

It should also be noted that the Lagrangian for a moving system is not unique; however, the study of how the various Lagrangians for a given moving system are related is not part of this walk.

Ref. 163

By the way, the letter q for position and p for momentum were introduced in physics by the mathematician Carl Jacobi (b. 1804 Potsdam, d. 1851 Berlin).

** This idea was ridiculed by the French philosopher Voltaire (1694–1778) in his lucid writings, notably in the brilliant book *Candide*, written in 1759, and still widely available.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 30 Some Lagrangians

System	Lagrangian	Variables
Free, non-relativistic mass point	$L = \frac{1}{2}mv^2$	mass m, speed $v = \mathrm{d}x/\mathrm{d}t$
Particle in potential	$L = \frac{1}{2}mv^2 - m\varphi(x)$	gravitational potential φ
Mass on spring	$L = \frac{1}{2}mv^2 - kx^2$	elongation x, spring constant k
Mass on frictionless table attached to spring	$L = \frac{1}{2}mv^2 - k(x^2 + y^2)$	spring constant k, coordinates x, y
Chain of masses and springs (simple model of atoms in a linear crystal)	$L = \frac{1}{2}m\sum v_i^2 + \frac{1}{2}m\omega^2 \sum_{i,j}(x_i - x_j)^2$	coordinates x_i, lattice frequency ω
Free, relativistic mass point	$L = -mc^2\sqrt{1 - v^2/c^2}$	mass m, speed v, speed of light c

Systems evolve by minimizing change. Change, or action, is the time integral of the Lagrangian. As a way to describe motion, the Lagrangian has several advantages over the evolution equation. First of all, the Lagrangian is usually more *compact* than writing the corresponding evolution equations. For example, only *one* Lagrangian is needed for one system, however many particles it includes. One makes fewer mistakes, especially sign mistakes, as one rapidly learns when performing calculations. Just try to write down the evolution equations for a chain of masses connected by springs; then compare the effort with a derivation using a Lagrangian. (The system is often studied because it behaves like a chain of atoms.) We will encounter another example shortly: David Hilbert took only a few weeks to deduce the equations of motion of general relativity using a Lagrangian, whereas Albert Einstein had worked for ten years searching for them directly.

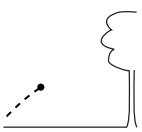
Challenge 384 ny

In addition, the description with a Lagrangian is valid with *any* set of coordinates describing the objects of investigation. The coordinates do not have to be Cartesian; they can be chosen as one prefers: cylindrical, spherical, hyperbolic, etc. These so-called *generalized coordinates* allow one to rapidly calculate the behaviour of many mechanical systems that are in practice too complicated to be described with Cartesian coordinates. For example, for programming the motion of robot arms, the angles of the joints provide a clearer description than Cartesian coordinates of the ends of the arms. Angles are non-Cartesian coordinates. They simplify calculations considerably: the task of finding the most economical way to move the hand of a robot from one point to another can be solved much more easily with angular variables.

More importantly, the Lagrangian allows one to quickly deduce the essential properties of a system, namely, its *symmetries* and its *conserved quantities*. We will develop this important idea shortly, and use it regularly throughout our walk.

Page 216

Finally, the Lagrangian formulation can be generalized to encompass *all types of interactions*. Since the concepts of kinetic and potential energy are general, the principle of least action can be used in electricity, magnetism and optics as well as mechanics. The principle of least action is central to general relativity and to quantum theory, and allows one to easily relate both fields to classical mechanics.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

As the principle of least action became well known, people applied it to an ever-increasing number of problems. Today, Lagrangians are used in everything from the study of elementary particle collisions to the programming of robot motion in artificial intelligence. However, we should not forget that despite its remarkable simplicity and usefulness, the Lagrangian formulation is *equivalent* to the evolution equations. It is neither more general nor more specific. In particular, it is *not an explanation* for any type of motion, but only a different view of it. In fact, the search of a new physical 'law' of motion is *just* the search for a new Lagrangian. This makes sense, as the description of nature always requires the description of change. Change in nature is always described by actions and Lagrangians.

Ref. 160

Challenge 385 s

The principle of least action states that the action is minimal when the end point of the motion, and in particular the time between them, are fixed. It is less well known that the reciprocal principle also holds: if the action is kept fixed, the elapsed time is maximal. Can you show this?

Ref. 164

Challenge 386 ny

Even though the principle of least action is not an explanation of motion, it somehow calls for one. We need some patience, though. *Why* nature follows the principle of least action, and *how* it does so, will become clear when we explore quantum theory.

Why is motion so often bounded?

> The optimist thinks this is the best of all possible worlds, and the pessimist knows it.
> Robert Oppenheimer

Looking around ourselves on Earth or in the sky, we find that matter is not evenly distributed. Matter tends to be near other matter: it is lumped together in *aggregates*. Some major examples of aggregates are listed in Figure 143 and Table 31. All aggregates have mass and size. In the mass–size diagram of Figure 143, both scales are logarithmic. One notes three straight lines: a line $m \sim l$ extending from the Planck mass* upwards, via black holes, to the universe itself; a line $m \sim 1/l$ extending from the Planck mass downwards, to the lightest possible aggregate; and the usual matter line with $m \sim l^3$, extending from atoms upwards, via everyday objects, the Earth to the Sun. The first of the lines, the black hole limit, is explained by general relativity; the last two, the aggregate limit and the common matter line, by quantum theory.**

Ref. 166

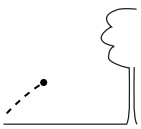
The aggregates outside the common matter line also show that the stronger the interaction that keeps the components together, the smaller the aggregate. But why is matter mainly found in lumps?

First of all, aggregates form because of the existence of *attractive* interactions between objects. Secondly, they form because of *friction*: when two components approach, an aggregate can only be formed if the released energy can be changed into heat. Thirdly, aggregates have a finite size because of *repulsive* effects that prevent the components from collapsing completely. Together, these three factors ensure that bound motion is much more common than unbound, 'free' motion.

Page 912

* The Planck mass is given by $m_{\text{Pl}} = \sqrt{\hbar c/G} = 21.767(16)\,\mu\text{g}$.

** Figure 143 suggests that domains beyond physics exist; we will discover later on that this is not the case, as mass and size are not definable in those domains.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

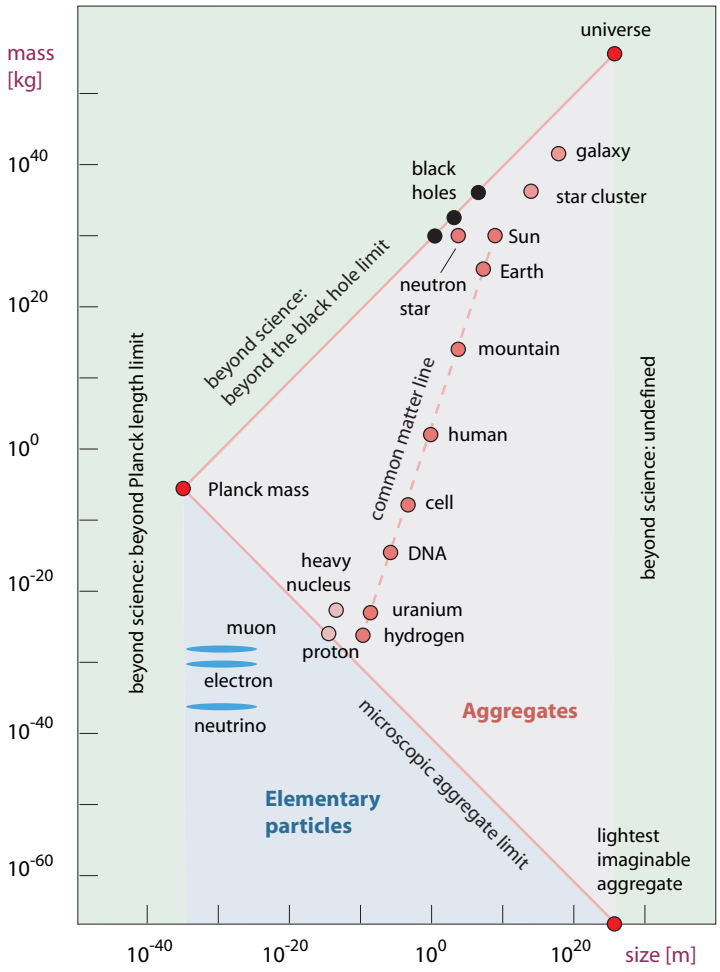


FIGURE 143 Elementary particles and aggregates found in nature

Only three types of attraction lead to aggregates: gravity, the attraction of electric charges, and the strong nuclear interaction. Similarly, only three types of repulsion are observed: rotation, pressure, and the Pauli exclusion principle (which we will encounter later on). Of the nine possible combinations of attraction and repulsion, not all appear in nature. Can you find out which ones are missing from Figure 143 and Table 31, and why?

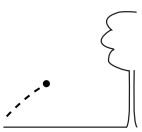
Page 1069

Challenge 387 s

Together, attraction, friction and repulsion imply that change and action are minimized when objects come and stay together. The principle of least action thus implies the stability of aggregates. By the way, formation history also explains why so many aggregates *rotate*. Can you tell why?

Challenge 388 ny

But why does friction exist at all? And why do attractive and repulsive interactions exist? And why is it – as it would appear from the above – that in some distant past matter was *not* found in lumps? In order to answer these questions, we must first study



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

another global property of motion: symmetry.

TABLE 31 Some major aggregates observed in nature

AGGREGATE	SIZE (DIAMETER)	OBS. NUM.	CONSTITUENTS
gravitationally bound aggregates			
matter across universe	*c.* 100 Ym	1	superclusters of galaxies, hydrogen and helium atoms
quasar	10^{12} to 10^{14} m	$20 \cdot 10^6$	baryons and leptons

mesons	*c.* 10^{-15} m	n.a.	quarks
neutron stars: see above			

a. Only in 1994 was the first evidence found for objects circling stars other than our Sun; of over 200 *extrasolar planets* found so far, most are found around F, G and K stars, including neutron stars. For example, three objects circle the pulsar PSR 1257+12, and a matter ring circles the star β Pictoris. The objects seem to be dark stars, brown dwarfs or large gas planets like Jupiter. Due to the limitations of observation systems, none of the systems found so far form solar systems of the type we live in. In fact, only a few Earth-like planets have been found so far.

Ref. 167

b. The Sun is among the brightest 7 % of stars. Of all stars, 80 %, are red M dwarfs, 8 % are orange K dwarfs, and 5 % are white D dwarfs: these are all faint. Almost all stars visible in the night sky belong to the bright 7 %. Some of these are from the rare blue O class or blue B class (such as Spica, Regulus and Rigel); 0.7 % consist of the bright, white A class (such as Sirius, Vega and Altair); 2 % are of the yellow–white F class (such as Canopus, Procyon and Polaris); 3.5 % are of the yellow G class (like Alpha Centauri, Capella or the Sun). Exceptions include the few visible K giants, such as Arcturus and Aldebaran, and the rare M supergiants, such as Betelgeuse and Antares. More on stars later on.

Page 593

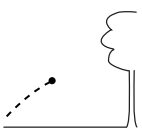
c. For more details on *microscopic* aggregates, see the table of composites in Appendix E.

d. It is estimated that there are about 10^9 asteroids (or planetoids) larger than 1 km and about 10^{20} that are heavier than 100 kg. By the way, no asteroids between Mercury and the Sun – the hypothetical *Vulcanoids* – have been found so far.

Ref. 168

CURIOSITIES AND FUN CHALLENGES ABOUT LAGRANGIANS

When Lagrange published his book *Mécanique analytique*, in 1788, it formed one of the high points in the history of mechanics. He was proud of having written a systematic exposition of mechanics without a single figure. Obviously the book was difficult to read and was not a sales success. Therefore his methods took another generation to come into general use.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

Given that action is the basic quantity describing motion, we can define energy as action per unit time, and momentum as action per unit distance. The *energy* of a system thus describes how much it changes over time, and the *momentum* how much it changes over distance. What are angular momentum and rotational energy?

Challenge 389 s

* *

'In nature, effects of telekinesis or prayer are impossible, as in most cases the change inside the brain is much smaller than the change claimed in the outside world.' Is this argument correct?

Challenge 390 s

* *

In Galilean physics, the Lagrangian is the difference between kinetic and potential energy. Later on, this definition will be generalized in a way that sharpens our understanding of this distinction: the Lagrangian becomes the difference between a term for free particles and a term due to their interactions. In other words, particle motion is a continuous compromise between what the particle would do if it were free and what other particles want it to do. In this respect, particles behave a lot like humans beings.

* *

Challenge 391 ny Explain: why is $T + U$ constant, whereas $T - U$ is minimal?

* *

In nature, the sum $T + U$ of kinetic and potential energy is *constant* during motion (for closed systems), whereas the average of the difference $T - U$ is *minimal*. Is it possible to deduce, by combining these two facts, that systems tend to a state with minimum potential energy?

Challenge 392 ny

* *

Another minimization principle can be used to understand the construction of animal bodies, especially their size and the proportions of their inner structures. For example, the heart pulse and breathing frequency both vary with animal mass m as $m^{-1/4}$, and the dissipated power varies as $m^{3/4}$. It turns out that such exponents result from three properties of living beings. First, they transport energy and material through the organism via a branched network of vessels: a few large ones, and increasingly many smaller ones. Secondly, the vessels all have the same minimum size. And thirdly, the networks are optimized in order to minimize the energy needed for transport. Together, these relations explain many additional scaling rules; they might also explain why animal lifespan scales as $m^{-1/4}$, or why most mammals have roughly the same number of heart beats in a lifetime.

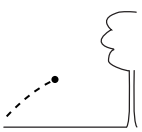
Ref. 169

A competing explanation, using a different minimization principle, states that quarter powers arise in any network built in order that the flow arrives to the destination by the most direct path.

Ref. 170

* *

The minimization principle for the motion of light is even more beautiful: light always



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

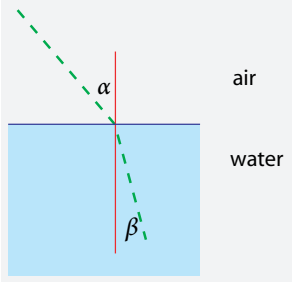


FIGURE 144 Refraction of light is due to travel-time optimization

takes the path that requires the shortest travel time. It was known long ago that this idea describes exactly how light changes direction when it moves from air to water. In water, light moves more slowly; the speed ratio between air and water is called the *refractive index* of water. The refractive index, usually abbreviated n, is material-dependent. The value for water is about 1.3. This speed ratio, together with the minimum-time principle, leads to the 'law' of refraction, a simple relation between the sines of the two angles. Challenge 393 s Can you deduce it? (In fact, the exact definition of the refractive index is with respect to Challenge 394 s vacuum, not to air. But the difference is negligible: can you imagine why?)

For diamond, the refractive index is 2.4. The high value is one reason for the sparkle Challenge 395 s of diamonds cut with the 57-face *brilliant* cut. Can you think of some other reasons?

* *

Can you confirm that all the mentioned minimization principles – that for the growth of trees, that for the networks inside animals, that for the motion of light – are special Challenge 396 s cases of the principle of least action? In fact, this is the case for *all* known minimization principles in nature. Each of them, like the principle of least action, is a principle of least change.

* *

In Galilean physics, the value of the action depends on the speed of the observer, but not on his position or orientation. But the action, when properly defined, should *not* depend on the observer. All observers should agree on the value of the observed change. Only special relativity will fulfil the requirement that action be independent of the observer's Challenge 397 s speed. How will the relativistic action be defined?

* *

Measuring all the change that is going on in the universe presupposes that the universe Challenge 398 s is a physical system. Is this the case?

* *

One motion for which action is particularly well minimized in nature is dear to us: walk- Ref. 171 ing. Extensive research efforts try to design robots which copy the energy saving functioning and control of human legs. For an example, see the website by Tao Geng at www.cn.stir.ac.uk/~tgeng/research.html.

* *

Challenge 399 d Can you prove the following integration challenge?

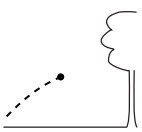
$$\int_0^{\varphi} \sec t \, dt = \ln \tan\left(\frac{\pi}{4} + \frac{\varphi}{2}\right) \tag{68}$$

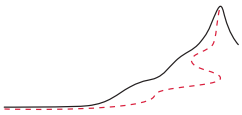
Summary on action

Systems move by minimizing change. Change, or action, is the time average of kinetic energy minus potential energy. The statement 'motion minimizes change' contains motion's predictability, its continuity, and its simplicity.

In the next sections we show that change minimization also implies observer-invariance, conservation, mirror-invariance, reversibility and relativity of motion.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009





Chapter 9

MOTION AND SYMMETRY

The second way to describe motion globally is to describe it in such a way that *all* observers agree. Now, whenever an observation stays the same when changing from one observer to another, we call the observation *symmetric*.

Symmetry is invariance after change. Change of observer or point of view is one such possible change, as can be some change operated on the observation itself. For example, a forget-me-not flower, shown in Figure 145, is symmetrical because it looks the same after turning it, or after turning around it, by 72 degrees; many fruit tree flowers have the same symmetry. One also says that under certain changes of viewpoint the flower has an *invariant property*, namely its shape. If many such viewpoints are possible, one talks about a *high* symmetry, otherwise a *low* symmetry. For example, a four-leaf clover has a higher symmetry than a usual, three-leaf one. In physics, the viewpoints are often called *frames of reference*.

When we speak about symmetry in everyday life, in architecture or in the arts we usually mean mirror symmetry, rotational symmetry or some combination. These are *geometric symmetries*. Like all symmetries, geometric symmetries imply invariance under specific change operations. The complete list of geometric symmetries is known since a long time. Ref. 177 Table 32 gives an overview of the basic types. Additional geometric symmetries include *colour symmetries*, where colours are exchanged, and *spin groups*, where symmetrical objects do not contain only points but also spins, with their special behaviour under rotations. Also combinations with scale symmetry, as they appear in fractals, and variations on curved backgrounds are extension of the basic table.

A *high* symmetry means that *many* possible changes leave an observation invariant. At first sight, not many objects or observations in nature seem to be symmetrical: after all, geometric symmetry is more the exception than the rule. But this is a fallacy. On the contrary, we can deduce that nature as a whole is symmetric from the simple fact that we have the ability to talk about it! Challenge 400 s Moreover, the symmetry of nature is considerably higher than that of a forget-me-not or of any other symmetry from Table 32. A consequence of this high symmetry is, among others, the famous expression $E_0 = mc^2$.

Why can we think and talk about the world?

> The hidden harmony is stronger than the apparent.

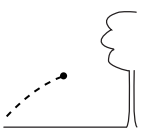
TABLE 32 The classification and the number of simple geometric symmetries

Dimension	Repetition types	Translations			
		0 point groups	1 line groups	2 plane groups	3 space groups
1	1 row	2	2	n.a.	n.a.
2	5 nets	10 crystal groups	7 friezes	17 wall-papers	n.a.
3	14 lattices	32 crystal groups	75 rods	80 layers	230 crystal structures

Why can we understand somebody when he is talking about the world, even though we are not in his shoes? We can for two reasons: because most things look *similar* from different viewpoints, and because most of us have already had similar experiences *beforehand*.

'Similar' means that what *we* and what *others* observe somehow correspond. In other words, many aspects of observations do not depend on viewpoint. For example, the number of petals of a flower has the same value for all observers. We can therefore say that this quantity has the highest possible symmetry. We will see below that mass is another such example. Observables with the highest possible symmetry are called *scalars* in physics. Other aspects change from observer to observer. For example, the apparent size varies with the distance of observation. However, the actual size is observer-independent. In general terms, any type of *viewpoint-independence* is a form of symmetry, and the observation that two people looking at the same thing from different viewpoints can understand each other proves that nature is symmetric. We start to explore the details of this symmetry in this section and we will continue during most of the rest of our hike.

In the world around us, we note another general property: not only does the same phenomenon look similar to different observers, but *different* phenomena look similar



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

to the *same* observer. For example, we know that if fire burns the finger in the kitchen, it will do so outside the house as well, and also in other places and at other times. Nature shows *reproducibility*. Nature shows no surprises. In fact, our memory and our thinking are only possible because of this basic property of nature. (Can you confirm this?) As we will see, reproducibility leads to additional strong restrictions on the description of nature.

Challenge 401 s

Without viewpoint-independence and reproducibility, talking to others or to oneself would be impossible. Even more importantly, we will discover that viewpoint-independence and reproducibility do more than determine the possibility of talking to each other: they also fix the *content* of what we can say to each other. In other words, we will see that our description of nature follows logically, almost without choice, from the simple fact that we can talk about nature to our friends.

Viewpoints

> Toleranz ... ist der Verdacht der andere könnte Recht haben.*
>
> Kurt Tucholski (1890–1935), German writer

> Toleranz – eine Stärke, die man vor allem dem politischen Gegner wünscht.**
>
> Wolfram Weidner (b. 1925) German journalist

When a young human starts to meet other people in childhood, he quickly finds out that certain experiences are shared, while others, such as dreams, are not. Learning to make this distinction is one of the adventures of human life. In these pages, we concentrate on a section of the first type of experiences: *physical* observations. However, even among these, distinctions are to be made. In daily life we are used to assuming that weights, volumes, lengths and time intervals are independent of the viewpoint of the observer. We can talk about these observed quantities to anybody, and there are no disagreements over their values, provided they have been measured correctly. However, other quantities do depend on the observer. Imagine talking to a friend after he jumped from one of the trees along our path, while he is still falling downwards. He will say that the forest floor is approaching with high speed, whereas the observer below will maintain that the floor is stationary. Obviously, the difference between the statements is due to their different viewpoints. The velocity of an object (in this example that of the forest floor or of the friend himself) is thus a less symmetric property than weight or size. Not all observers agree on its value.

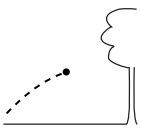
In the case of viewpoint-dependent observations, understanding is still possible with the help of a little effort: each observer can *imagine* observing from the point of view of the other, and *check* whether the imagined result agrees with the statement of the other.*** If the statement thus imagined and the actual statement of the other observer agree, the observations are consistent, and the difference in statements is due only to the

* 'Tolerance ... is the suspicion that the other might be right.'

** 'Tolerance – a strength one mainly wishes to political opponents.'

*** Humans develop the ability to imagine that others can be in situations *different* from their own at the age of about four years. Therefore, before the age of four, humans are unable to conceive special relativity; afterwards, they can.

Ref. 173



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

different viewpoints; otherwise, the difference is fundamental, and they cannot agree or talk. Using this approach, you can even argue whether human feelings, judgements, or tastes arise from fundamental differences or not. Challenge 402 s

The distinction between viewpoint-independent (invariant) and viewpoint-dependent quantities is an essential one. Invariant quantities, such as mass or shape, describe *intrinsic* properties, and quantities depending on the observer make up the *state* of the system. Therefore, we must answer the following questions in order to find a *complete* description of the state of a physical system:

— Which viewpoints are possible?
— How are descriptions transformed from one viewpoint to another?
— Which observables do these symmetries admit?
— What do these results tell us about motion?

In the discussion so far, we have studied viewpoints differing in location, in orientation, in time and, most importantly, in motion. With respect to each other, observers can be at rest, move with constant speed, or accelerate. These 'concrete' changes of viewpoint are those we will study first. In this case the requirement of consistency of observations made by different observers is called the *principle of relativity*. The symmetries associated with this type of invariance are also called *external* symmetries. They are listed in Table 34. Page 132 Page 220

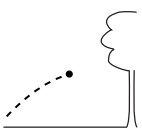
A second class of fundamental changes of viewpoint concerns 'abstract' changes. Viewpoints can differ by the mathematical description used: such changes are called *changes of gauge*. They will be introduced first in the section on electrodynamics. Again, it is required that all statements be consistent across different mathematical descriptions. This requirement of consistency is called the *principle of gauge invariance*. The associated symmetries are called *internal* symmetries. Page 712

The third class of changes, whose importance may not be evident from everyday life, is that of the behaviour of a system under exchange of its parts. The associated invariance is called *permutation symmetry*. It is a *discrete* symmetry, and we will encounter it in the part of our adventure that deals with quantum theory. Page 1052

The three consistency requirements described above are called 'principles' because these basic statements are so strong that they almost completely determine the 'laws' of physics, as we will see shortly. Later on we will discover that looking for a complete description of the state of objects will also yield a complete description of their *intrinsic* properties. But enough of introduction: let us come to the heart of the topic.

Symmetries and groups

Since we are looking for a complete description of motion, we need to understand and describe the full set of symmetries of nature. A system is said to be symmetric or to possess a *symmetry* if it appears identical when observed from different viewpoints. We also say that the system possesses an *invariance* under change from one viewpoint to the other. Viewpoint changes are called *symmetry operations* or *transformations*. A symmetry is thus a transformation, or more generally, a set of transformations. However, it is more than that: the successive application of two symmetry operations is another symmetry operation. To be more precise, a symmetry is a set $G = \{a, b, c, \ldots\}$ of elements, the transformations, together with a binary operation $\circ$ called *concatenation* or *multiplication* and



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

pronounced 'after' or 'times', in which the following properties hold for all elements a, b and c:

$$\begin{aligned} \textit{associativity}, \text{ i.e.,} \quad & (a \circ b) \circ c = a \circ (b \circ c) \\ \text{a } \textit{neutral element } e \text{ exists such that} \quad & e \circ a = a \circ e = a \\ \text{an } \textit{inverse element } a^{-1} \text{ exists such that} \quad & a^{-1} \circ a = a \circ a^{-1} = e \quad . \end{aligned} \tag{69}$$

Any set that fulfils these three defining properties, or axioms, is called a *(mathematical) group*. Historically, the notion of group was the first example of a mathematical structure which was defined in a completely abstract manner.* Can you give an example of a group taken from daily life? Groups appear frequently in physics and mathematics, because symmetries are almost everywhere, as we will see.** Can you list the symmetry operations of the pattern of Figure 146?

Challenge 403 s
Ref. 174
Challenge 404 s

Representations

Looking at a symmetric and composed system such as the one shown in Figure 146, we notice that each of its parts, for example each red patch, belongs to a set of similar objects, usually called a *multiplet*. Taken as a whole, the multiplet has (at least) the symmetry properties of the whole system. For some of the coloured patches in Figure 146 we need four objects to make up a full multiplet, whereas for others we need two, or only one, as in the case of the central star. In fact, in any symmetric system each part can be classified according to what type of multiplet it belongs to. Throughout our mountain ascent we will perform the same classification with every part of nature, with ever-increasing precision.

Challenge 405 e

A *multiplet* is a set of parts that transform into each other under all symmetry transformations. Mathematicians often call abstract multiplets *representations*. By specifying to which multiplet a component belongs, we describe in which way the component is part of the whole system. Let us see how this classification is achieved.

In mathematical language, symmetry transformations are often described by matrices. For example, in the plane, a reflection along the first diagonal is represented by the matrix

$$D(\text{refl}) = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix} , \tag{70}$$

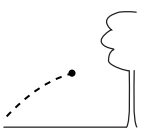
since every point (x, y) becomes transformed to (y, x) when multiplied by the matrix

* The term is due to Evariste Galois (1811–1832), the structure to Augustin-Louis Cauchy (1789–1857) and the axiomatic definition to Arthur Cayley (1821–1895).

** In principle, mathematical groups need not be symmetry groups; but it can be proven that all groups can be seen as transformation groups on some suitably defined mathematical space, so that in mathematics we can use the terms 'symmetry group' and 'group' interchangeably.

A group is called *Abelian* if its concatenation operation is commutative, i.e., if $a \circ b = b \circ a$ for all pairs of elements a and b. In this case the concatenation is sometimes called *addition*. Do rotations form an Abelian group?

A subset $G_1 \subset G$ of a group G can itself be a group; one then calls it a *subgroup* and often says sloppily that G is *larger* than G_1 or that G is a *higher* symmetry group than G_1.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

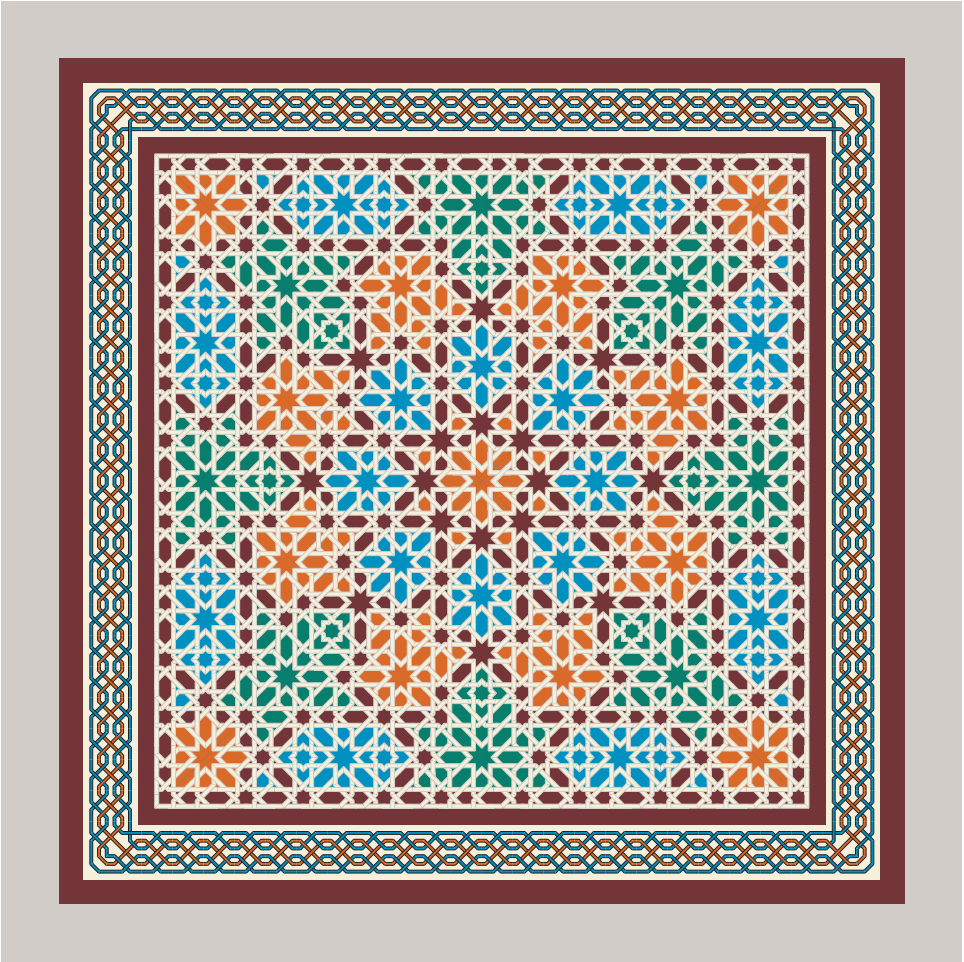


FIGURE 146 A Hispano–Arabic ornament from the Governor's Palace in Sevilla (© Christoph Schiller)

Challenge 406 e

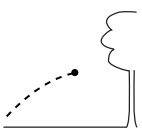
$D(\text{refl})$. Therefore, for a mathematician a *representation* of a symmetry group G is an assignment of a matrix $D(a)$ to each group element a such that the representation of the concatenation of two elements a and b is the product of the representations D of the elements:

$$D(a \circ b) = D(a)D(b) \ . \tag{71}$$

For example, the matrix of equation (70), together with the corresponding matrices for all the other symmetry operations, have this property.*

* There are some obvious, but important, side conditions for a representation: the matrices $D(a)$ must be invertible, or non-singular, and the identity operation of G must be mapped to the unit matrix. In even more compact language one says that a representation is a *homomorphism* from G into the group of non-singular or invertible matrices. A matrix D is invertible if its determinant $\det D$ is not zero.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



For every symmetry group, the construction and classification of all possible representations is an important task. It corresponds to the classification of all possible multiplets a symmetric system can be made of. In this way, understanding the classification of all multiplets and parts which can appear in Figure 146 will teach us how to classify all possible parts of which an object or an example of motion can be composed!

A representation D is called *unitary* if all matrices $D(a)$ are unitary.* Almost all representations appearing in physics, with only a handful of exceptions, are unitary: this term is the most restrictive, since it specifies that the corresponding transformations are one-to-one and invertible, which means that one observer never sees more or less than another. Obviously, if an observer can talk to a second one, the second one can also talk to the first.

The final important property of a multiplet, or representation, concerns its structure. If a multiplet can be seen as composed of sub-multiplets, it is called *reducible*, else *irreducible*; the same is said about representations. The irreducible representations obviously cannot be decomposed any further. For example, the (approximate) symmetry group of Figure 146, commonly called D_4, has eight elements. It has the general, faithful, unitary and irreducible matrix representation

Challenge 407 e

$$\begin{pmatrix} \cos n\pi/2 & -\sin n\pi/2 \\ \sin n\pi/2 & \cos n\pi/2 \end{pmatrix} \; n = 0..3, \begin{pmatrix} -1 & 0 \\ 0 & 1 \end{pmatrix}, \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \begin{pmatrix} 0 & -1 \\ -1 & 0 \end{pmatrix}. \tag{73}$$

The representation is an *octet*. The complete list of possible irreducible representations of the group D_4 is given by *singlets*, *doublets* and *quartets*. Can you find them all? These representations allow the classification of all the white and black ribbons that appear in the figure, as well as all the coloured patches. The most symmetric elements are singlets, the least symmetric ones are members of the quartets. The complete system is always a singlet as well.

Challenge 408 ny

With these concepts we are ready to talk about motion with improved precision.

In general, if a mapping f from a group G to another G' satisfies

$$f(a \circ_G b) = f(a) \circ_{G'} f(b) \,, \tag{72}$$

the mapping f is called an *homomorphism*. A homomorphism f that is one-to-one (injective) and onto (surjective) is called a *isomorphism*. If a representation is also injective, it is called *faithful*, *true* or *proper*.

In the same way as groups, more complex mathematical structures such as rings, fields and associative algebras may also be represented by suitable classes of matrices. A representation of the field of complex numbers is given in Appendix B.

* The *transpose* A^T of a matrix A is defined element-by-element by $(A^T)_{ik} = A_{ki}$. The *complex conjugate* A^* of a matrix A is defined by $(A^*)_{ik} = (A_{ik})^*$. The *adjoint* $A^\dagger$ of a matrix A is defined by $A^\dagger = (A^T)^*$. A matrix is called *symmetric* if $A^T = A$, *orthogonal* if $A^T = A^{-1}$, *Hermitean* or *self-adjoint* (the two are synonymous in all physical applications) if $A^\dagger = A$ (Hermitean matrices have real eigenvalues), and *unitary* if $A^\dagger = A^{-1}$. Unitary matrices have eigenvalues of norm one. Multiplication by a unitary matrix is a one-to-one mapping; since the time evolution of physical systems is a mapping from one time to another, evolution is always described by a unitary matrix. A *real* matrix obeys $A^* = A$, an *antisymmetric* or *skew-symmetric* matrix is defined by $A^T = -A$, an *anti-Hermitean* matrix by $A^\dagger = -A$ and an *anti-unitary* matrix by $A^\dagger = -A^{-1}$. All the mappings described by these special types of matrices are one-to-one. A matrix is *singular*, i.e., not one-to-one, if $\det A = 0$.

TABLE 33 Correspondences between the symmetries of an ornament, a flower and nature as a whole

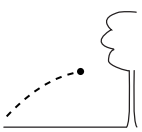
System	Hispano–Arabic pattern	Flower	Motion
Structure and components	set of ribbons and patches	set of petals, stem	motion path and observables
System symmetry	pattern symmetry	flower symmetry	symmetry of Lagrangian
Mathematical description of the symmetry group	D_4	C_5	in Galilean relativity: position, orientation, instant and velocity changes
Invariants	number of multiplet elements	petal number	number of coordinates, magnitude of scalars, vectors and tensors
Representations of the components	multiplet types of elements	multiplet types of components	tensors, including scalars and vectors
Most symmetric representation	singlet	part with circular symmetry	scalar
Simplest faithful representation	quartet	quintet	vector
Least symmetric representation	quartet	quintet	no limit (tensor of infinite rank)

Symmetries, motion and Galilean physics

Every day we experience that we are able to talk to each other about motion. It must therefore be possible to find an *invariant* quantity describing it. We already know it: it is the *action*, the measure of change. For example, lighting a match is a change. The magnitude of the change is the same whether the match is lit here or there, in one direction or another, today or tomorrow. Indeed, the (Galilean) action is a number whose value is the same for each observer *at rest*, independent of his orientation or the time at which he makes his observation.

In the case of the Arabic pattern of Figure 146, the symmetry allows us to deduce the list of multiplets, or representations, that can be its building blocks. This approach must be possible for motion as well. In the case of the Arabic pattern, from the various possible observation viewpoints, we deduced the classification of the ribbons into singlets, doublets, etc. For a moving system, the building blocks, corresponding to the ribbons, are the *observables*. Since we observe that nature is symmetric under many different changes of viewpoint, we can classify all observables. To do so, we first need to take the list of all viewpoint transformations and then deduce the list of all their representations.

Our everyday life shows that the world stays unchanged after changes in position,



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

orientation and instant of observation. One also speaks of space translation invariance, rotation invariance and time translation invariance. These transformations are different from those of the Arabic pattern in two respects: they are *continuous* and they are *unbounded*. As a result, their representations will generally be continuously variable and without bounds: they will be *quantities* or *magnitudes*. In other words, observables will be constructed with *numbers*. In this way we have deduced why numbers are *necessary* for any description of motion.*

Since observers can differ in orientation, most representations will be objects possessing a direction. To cut a long story short, the symmetry under change of observation position, orientation or instant leads to the result that all observables are either 'scalars', 'vectors' or higher-order 'tensors.'**

A *scalar* is an observable quantity which stays the same for all observers: it corresponds to a singlet. Examples are the mass or the charge of an object, the distance between two points, the distance of the horizon, and many others. Their possible values are (usually) continuous, unbounded and without direction. Other examples of scalars are the potential at a point and the temperature at a point. Velocity is obviously not a scalar; nor is the coordinate of a point. Can you find more examples and counter-examples?

Challenge 410 s

Energy is a puzzling observable. It is a scalar if only changes of place, orientation and instant of observation are considered. But energy is not a scalar if changes of observer speed are included. Nobody ever searched for a generalization of energy that is a scalar also for moving observers. Only Albert Einstein discovered it, completely by accident. More about this issue shortly.

Any quantity which has a magnitude and a direction and which 'stays the same' with respect to the environment when changing viewpoint is a *vector*. For example, the arrow between two fixed points on the floor is a vector. Its length is the same for all observers; its direction changes from observer to observer, but not with respect to its environment. On the other hand, the arrow between a tree and the place where a rainbow touches the Earth is *not* a vector, since that place does not stay fixed with respect to the environment, when the observer changes.

Mathematicians say that vectors are directed entities staying invariant under coordinate transformations. Velocities of objects, accelerations and field strength are examples of vectors. (Can you confirm this?) The magnitude of a vector is a scalar: it is the same for any observer. By the way, a famous and baffling result of nineteenth-century experiments is that the velocity of a light beam is *not* a vector like the velocity of a car; the velocity of a light beam is not a vector for Galilean transformations, . This mystery will be solved shortly.

Challenge 411 e

Tensors are generalized vectors. As an example, take the moment of inertia of an object. It specifies the dependence of the angular momentum on the angular velocity. For any object, doubling the magnitude of angular velocity doubles the magnitude of angular momentum; however, the two vectors are not parallel to each other if the object is not a sphere. In general, if any two vector quantities are proportional, in the sense that doubling the magnitude of one vector doubles the magnitude of the other, but without

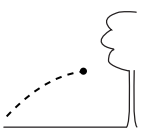
Page 104

Page 136

* Only scalars, in contrast to vectors and higher-order tensors, may also be quantities which only take a discrete set of values, such as +1 or −1 only. In short, only scalars may be *discrete* observables.

Challenge 409 e

** Later on, *spinors* will be added to, and complete, this list.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the two vectors being parallel to each other, then the proportionality 'factor' is a (second order) *tensor*. Like all proportionality factors, tensors have a magnitude. In addition, tensors have a direction and a *shape*: they describe the connection between the vectors they relate. Just as vectors are the simplest quantities with a magnitude and a direction, so tensors are the simplest quantities with a magnitude and with a direction depending on a second, chosen direction. Vectors can be visualized as oriented arrows; tensors can be visualized as oriented ellipsoids.* Can you name another example of tensor?

Challenge 413 s

Let us get back to the description of motion. Table 33 shows that in physical systems we always have to distinguish between the symmetry of the whole Lagrangian – corresponding to the symmetry of the complete pattern – and the representation of the observables – corresponding to the ribbon multiplets. Since the action must be a scalar, and since all observables must be tensors, Lagrangians contain sums and products of tensors only in combinations forming scalars. Lagrangians thus contain only scalar products or generalizations thereof. In short, Lagrangians always look like

$$L = \alpha\, a_i b^i + \beta\, c_{jk} d^{jk} + \gamma\, e_{lmn} f^{lmn} + \dots \tag{74}$$

where the indices attached to the variables a, b, c etc. always come in matching pairs to be summed over. (Therefore summation signs are usually simply left out.) The Greek letters represent constants. For example, the action of a free point particle in Galilean physics was given as

$$S = \int L \,\mathrm{d}t = \frac{m}{2} \int v^2 \,\mathrm{d}t \tag{75}$$

which is indeed of the form just mentioned. We will encounter many other cases during our study of motion.**

Galileo already understood that motion is also invariant under change of viewpoints with different velocity. However, the action just given does not reflect this. It took some

Page 132

* A rank-n tensor is the proportionality factor between a rank-1 tensor, i.e., between a vector, and an rank-$(n-1)$ tensor. Vectors and scalars are rank 1 and rank 0 tensors. Scalars can be pictured as spheres, vectors as arrows, and rank-2 tensors as ellipsoids. Tensors of higher rank correspond to more and more complex shapes.

A vector has the same length and direction for every observer; a tensor (of rank 2) has the same determinant, the same trace, and the same sum of diagonal subdeterminants for all observers.

A vector is described mathematically by a *list* of components; a tensor (of rank 2) is described by a *matrix* of components. The rank or order of a tensor thus gives the number of indices the observable has. Can you show this?

Challenge 412 e

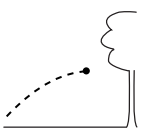
** By the way, is the usual list of possible observation viewpoints – namely different positions, different observation instants, different orientations, and different velocities – also *complete* for the action (75)? Surprisingly, the answer is no. One of the first who noted this fact was Niederer, in 1972. Studying the quantum theory of point particles, he found that even the action of a Galilean free point particle is invariant under some additional transformations. If the two observers use the coordinates $(t, \boldsymbol{x})$ and $(\tau, \boldsymbol{\xi})$, the action (75) is invariant under the transformations

Ref. 175

Challenge 414 ny

$$\boldsymbol{\xi} = \frac{\boldsymbol{r}\boldsymbol{x} + \boldsymbol{x}_0 + \boldsymbol{v}t}{\gamma t + \delta} \quad \text{and} \quad \tau = \frac{\alpha t + \beta}{\gamma t + \delta} \quad \text{with} \quad \boldsymbol{r}^T \boldsymbol{r} = \mathbf{1} \quad \text{and} \quad \alpha\delta - \beta\gamma = 1\,. \tag{76}$$

where $\boldsymbol{r}$ describes the rotation from the orientation of one observer to the other, $\boldsymbol{v}$ the velocity between the two observers, and $\boldsymbol{x}_0$ the vector between the two origins at time zero. This group contains two important



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

years to find out the correct generalization: it is given by the theory of special relativity. But before we study it, we need to finish the present topic.

Reproducibility, conservation and Noether's theorem

> I will leave my mass, charge and momentum to science.
>
> Graffito

The reproducibility of observations, i.e., the symmetry under change of instant of time or 'time translation invariance', is a case of viewpoint-independence. (That is not obvious; can you find its irreducible representations?) The connection has several important consequences. We have seen that symmetry implies invariance. It turns out that for *continuous* symmetries, such as time translation symmetry, this statement can be made more precise: for any continuous symmetry of the Lagrangian there is an associated conserved constant of motion and vice versa. The exact formulation of this connection is the theorem of Emmy Noether.* She found the result in 1915 when helping Albert Einstein and David Hilbert, who were both struggling and competing at constructing general relativity. However, the result applies to any type of Lagrangian.

Challenge 415 ny

Ref. 176

Noether investigated continuous symmetries depending on a continuous parameter b. A viewpoint transformation is a symmetry if the action S does not depend on the value of b. For example, changing position as

$$x \mapsto x + b \tag{78}$$

leaves the action

$$S_0 = \int T(v) - U(x)\,\mathrm{d}t \tag{79}$$

invariant, since $S(b) = S_0$. This situation implies that

$$\frac{\partial T}{\partial v} = p = \text{const} \quad ; \tag{80}$$

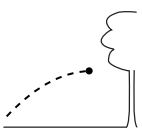
in short, symmetry under change of position implies conservation of momentum. The

special cases of transformations:

$$\begin{aligned} &\text{The connected, static Galilei group } \boldsymbol{\xi} = \boldsymbol{r}\boldsymbol{x} + \boldsymbol{x}_0 + \boldsymbol{v}t \quad \text{and} \quad \tau = t \\ &\text{The transformation group SL(2,R) } \boldsymbol{\xi} = \frac{\boldsymbol{x}}{\gamma t + \delta} \quad \text{and} \quad \tau = \frac{\alpha t + \beta}{\gamma t + \delta} \end{aligned} \tag{77}$$

The latter, three-parameter group includes *spatial inversion*, *dilations*, *time translation* and a set of time-dependent transformations such as $\boldsymbol{\xi} = \boldsymbol{x}/t$, $\tau = 1/t$ called *expansions*. Dilations and expansions are rarely mentioned, as they are symmetries of point particles only, and do not apply to everyday objects and systems. They will return to be of importance later on, however.

* Emmy Noether (b. 1882 Erlangen, d. 1935 Bryn Mayr), German mathematician. The theorem is only a sideline in her career which she dedicated mostly to number theory. The theorem also applies to gauge symmetries, where it states that to every gauge symmetry corresponds an identity of the equation of motion, and vice versa.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

converse is also true.

Challenge 416 ny In the case of symmetry under shift of observation instant, we find

$$T + U = \text{const} \quad ; \tag{81}$$

in other words, time translation invariance implies constant energy. Again, the converse is also correct. One also says that energy and momentum are the *generators* of time and space translations.

The conserved quantity for a continuous symmetry is sometimes called the *Noether charge*, because the term *charge* is used in theoretical physics to designate conserved extensive observables. So, energy and momentum are Noether charges. 'Electric charge', 'gravitational charge' (i.e., mass) and 'topological charge' are other common examples.

Challenge 417 s What is the conserved charge for rotation invariance?

We note that the expression 'energy is conserved' has several meanings. First of all, it means that the energy of a *single* free particle is constant in time. Secondly, it means that the total energy of any number of independent particles is constant. Finally, it means that the energy of a *system* of particles, i.e., including their interactions, is constant in time. Collisions are examples of the latter case. Noether's theorem makes all of these points at

Challenge 418 e the same time, as you can verify using the corresponding Lagrangians.

But Noether's theorem also makes, or rather repeats, an even stronger statement: if energy were not conserved, time could not be defined. The whole description of nature requires the existence of conserved quantities, as we noticed when we introduced the

Page 34 concepts of object, state and environment. For example, we defined objects as *permanent* entities, that is, as entities characterized by conserved quantities. We also saw that the

Page 186 introduction of time is possible only because in nature there are 'no surprises'. Noether's theorem describes exactly what such a 'surprise' would have to be: the non-conservation of energy. However, energy jumps have never been observed – not even at the quantum level.

Since symmetries are so important for the description of nature, Table 34 gives an overview of all the symmetries of nature we will encounter. Their main properties are also listed. Except for those marked as 'approximate' or 'speculative', an experimental proof of incorrectness of any of them would be a big surprise indeed.

TABLE 34 The symmetries of relativity and quantum theory with their properties; also the complete list of logical *inductions* used in the two fields

The same is true for a cube. Can you distinguish spheres and cubes by their rotation behaviour? Challenge 423 ny

* *

Is there a motion in nature whose symmetry is perfect? Challenge 424 ny

* *

Can you show that in two dimensions, *finite* objects can have only rotation and reflection symmetry, in contrast to *infinite* objects, which can have also translation and glide-reflection symmetry? Can you prove that for finite objects in two dimensions, if no rotation symmetry is present, there is only one reflection symmetry? And that all possible rotations are always about the same centre? Can you deduce from this that at least one point is unchanged in all symmetrical finite two-dimensionsal objects? Challenge 425 e

* *

Can you show that in three dimensions, *finite* objects can have only rotation, reflection, inversion and rotatory inversion symmetry, in contrast to *infinite* objects, which can have also translation, glide-reflection, and screw rotation symmetry? Can you prove that for finite objects in three dimensions, if no rotation symmetry is present, there is only one reflection plane? And that for all inversions or rotatory inversions the centre must lie on a rotation axis or on a reflection plane? Can you deduce from this that at least one point is unchanged in all symmetrical finite three-dimensional objects? Challenge 426 e

Parity and time invariance

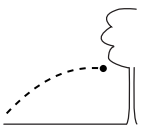
The table of symmetries also list two so-called *discrete* symmetries that are important for the discussion of motion.

How far can you throw a stone with your other hand? Most people have a preferred hand, and the differences are quite pronounced. Does nature have such a preference? In everyday life, the answer is clear: everything that happens can also happen the other way round. This has also been tested in precision experiments; it was found that everything happening through gravitation, electricity and magnetism can also happen in a mirrored way. There are no exceptions. For example, there are people with the heart on the right side; there are snails with left-handed houses; there are planets that rotate the other way. Astronomy and everyday life are *mirror-invariant*. One also says that gravitation and electromagnetism are *parity invariant*. (Later we will discover an exception to this statement.) Page 1277

Can things happen backwards? This question is not easy. A study of motion due to gravitation shows that such motion can always also happen in the reverse direction. In case of motion due to electricity and magnetism, such as the behaviour of atoms in gases and liquids, the question is more involved; we will discuss it in the section of thermodynamics.

Summary on symmetry

Symmetry is partial invariance to change. All possible changes, i.e., all possible symmetry transformations form a mathematical group.



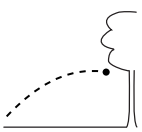
Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

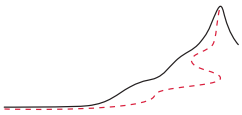
Since we can *talk* about nature we can deduce that above all, nature is symmetrical under time and space translations. Motion is universal. In addition, everyday observations are observed to be mirror symmetric and simple motions are symmetric under motion reversal.

From nature's symmetries, using Noether's theorem, we can deduce conserved 'charges'. These are energy, linear momentum and angular momentum. In other words, the definition of mass, space and time, together with their symmetry properties, is *equivalent* to the conservation of energy and momenta. Conservation and symmetry are two ways to express the same property of nature. To put it simply, our ability to talk about nature means that energy, linear momentum and angular momentum are conserved.

An most elegant way to uncover the 'laws' of nature is to search for nature's symmetries. In many historical cases, once this connection had been understood, physics made rapid progress. For example, Albert Einstein discovered the theory of relativity in this way, and Paul Dirac started off quantum electrodynamics. We will use the same method throughout our walk; in final third part we will uncover some symmetries which are even more mind-boggling than those of relativity. Now, though, we will move on to the next approach to a global description of motion.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009





Chapter 10

SIMPLE MOTIONS OF EXTENDED BODIES – OSCILLATIONS AND WAVES

We defined action, and thus change, as the integral of the Lagrangian, and the Lagrangian as the difference between kinetic and potential energy. One of the simplest systems in nature is a mass m attached to a (linear) spring. Its Lagrangian is given by

$$L = \frac{1}{2}mv^2 - kx^2 \,, \tag{82}$$

where k is a quantity characterizing the spring, the so-called spring constant. The Lagrangian is due to Robert Hooke, in the seventeenth century. Can you confirm it?

Challenge 427 e

The motion that results from this Lagrangian is periodic, and shown in Figure 147. The Lagrangian (82) thus describes the oscillation of the spring length. The motion is exactly the same as that of a long pendulum. It is called *harmonic motion*, because an object vibrating rapidly in this way produces a completely pure – or harmonic – musical sound. (The musical instrument producing the purest harmonic waves is the transverse flute. This instrument thus gives the best idea of how harmonic motion 'sounds'.) The graph of a harmonic or linear oscillation, shown in Figure 147, is called a *sine curve*; it can be seen as the basic building block of all oscillations. All other, non-harmonic oscillations in nature can be composed from sine curves, as we shall see shortly.

Page 229

Every oscillating motion continuously transforms kinetic energy into potential energy and vice versa. This is the case for the tides, the pendulum, or any radio receiver. But many oscillations also diminish in time: they are damped. Systems with large damping, such as the shock absorbers in cars, are used to avoid oscillations. Systems with *small* damping are useful for making precise and long-running clocks. The simplest measure of damping is the number of oscillations a system takes to reduce its amplitude to $1/e \approx 1/2.718$ times the original value. This characteristic number is the so-called *Q-factor*, named after the abbreviation of 'quality factor'. A poor Q-factor is 1 or less, an extremely good one is 100 000 or more. (Can you write down a simple Lagrangian for a damped oscillation with a given Q-factor?) In nature, damped oscillations do not usually keep constant frequency; however, for the simple pendulum this remains the case to a high degree of accuracy. The reason is that for a pendulum, the frequency does not depend significantly on the amplitude (as long as the amplitude is smaller than about 20°). This is one reason why pendulums are used as oscillators in mechanical clocks.

Challenge 428 ny

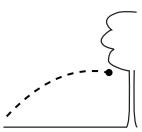
Obviously, for a good clock, the driving oscillation must not only show small damping, but must also be independent of temperature and be insensitive to other external influences. An important development of the twentieth century was the introduction of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 35 Some mechanical frequency values found in nature

Observation	Frequency
Sound frequencies in gas emitted by black holes	*c.* 1 fHz
Precision in measured vibration frequencies of the Sun	down to 2 nHz
Vibration frequencies of the Sun	down to *c.* 300 nHz
Vibration frequencies that disturb gravitational radiation detection	down to 3 μHz
Lowest vibration frequency of the Earth Ref. 178	309 μHz
Resonance frequency of stomach and internal organs (giving the 'sound in the belly' experience)	1 to 10 Hz
Common music tempo	2 Hz
Official value, or *standard pitch*, of musical note 'A' or 'la', following ISO 16 (and of the telephone line signal in many countries)	440 Hz
Common values of musical note 'A' or 'la' used by orchestras	442 to 451 Hz
Wing beat of tiny fly	*c.* 1000 Hz
Sound audible to young humans	20 Hz to 20 kHz
Sonar used by bats	up to over 100 kHz
Sonar used by dolphins	up to 150 kHz
Sound frequency used in ultrasound imaging	2 to 20 MHz
Quartz oscillator frequencies	20 kHz up to 350 MHz
Highest electronically generated frequency (with CMOS, in 2007)	324 GHz
Phonon (sound) frequencies measured in single crystals	up to 20 THz and more

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



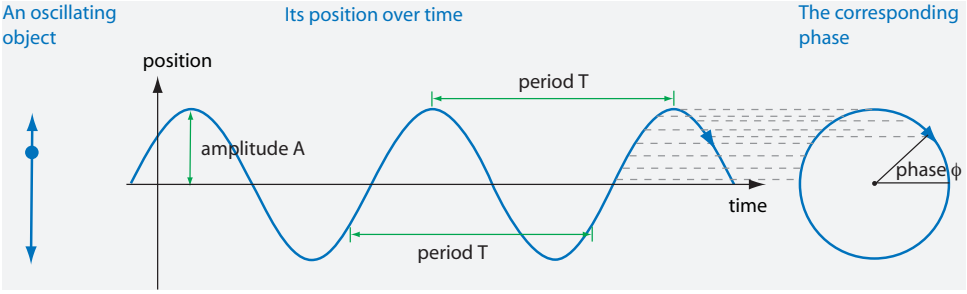


FIGURE 147 The simplest oscillation, the *linear* or *harmonic* oscillation: how position changes over time, and how it is related to rotation

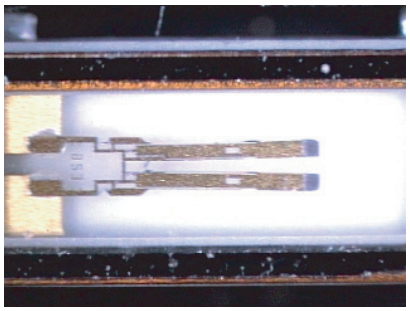

FIGURE 148 The interior of a commercial quartz oscillator, driven at high amplitude (QuickTime film © Microcrystal)

quartz crystals as oscillators. Technical quartzes are crystals of the size of a few grains of sand; they can be made to oscillate by applying an electric signal. They have little temperature dependence and a large Q-factor, and therefore low energy consumption, so that precise clocks can now run on small batteries.

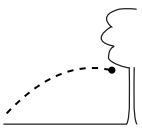
Every harmonic oscillation is described by three quantities: the *amplitude*, the *period* (the inverse of the frequency) and the *phase*. The phase distinguishes oscillations of the same amplitude and period; it defines at what time the oscillation starts. Figure 147 shows how a harmonic oscillation is related to an imaginary rotation. As a result, the phase is best described by an angle between 0 and 2π.

All systems that oscillate also emit waves. In fact, oscillations only appear in extended systems, and oscillations are only the simplest of motions of extended systems. The general repetitive motion of an extended system is the wave.

Waves and their motion

Waves are travelling imbalances, or, equivalently, travelling oscillations. Waves move, even though the substrate does not move. Every wave can be seen as a superposition of *harmonic* waves. Can you describe the difference in wave shape between a pure harmonic tone, a musical sound, a noise and an explosion? Every sound effect can be thought of as being composed of harmonic waves. Harmonic waves, also called *sine waves* or *linear waves*, are the building blocks of which all internal motions of an extended body are

Challenge 429 e



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

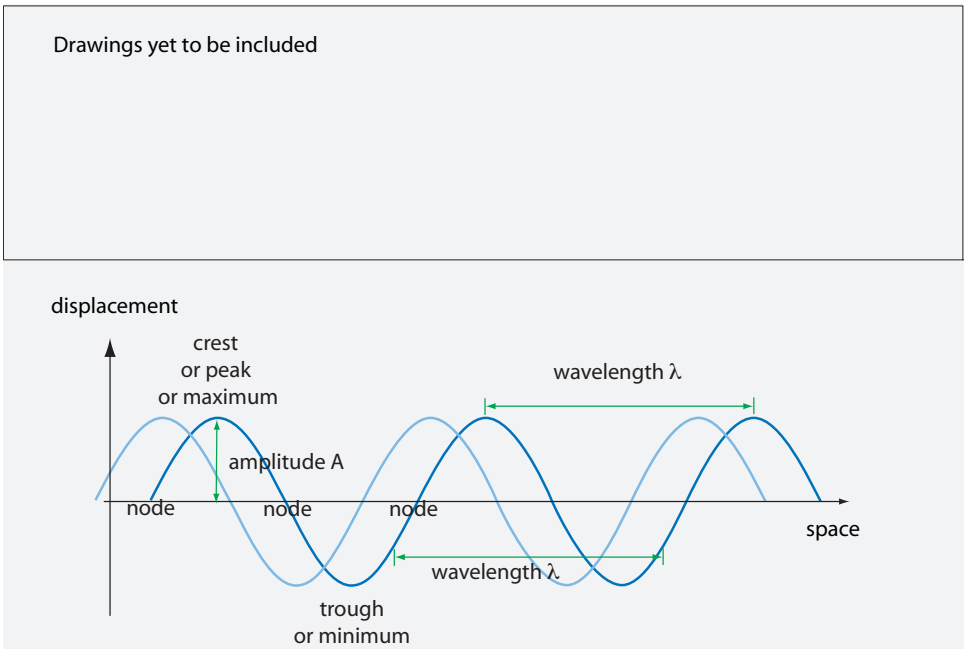


FIGURE 149 Decomposing a general periodic signal (left) and a general, non-periodic signal (right) into the simplest, or *harmonic* waves, and their details (bottom)

constructed.

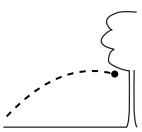
Every harmonic wave is characterized by an oscillation *frequency*, a propagation *velocity*, a *wavelength*, and a *phase*, as can be deduced from Figure 149. Low-amplitude water waves show this most clearly. In a harmonic wave, every position performs a harmonic oscillation. The phase of a wave specifies the position of the wave (or a crest) at a given time. It is an angle between 0 and 2π. How are frequency and wavelength related in a wave?

Challenge 430 e

Waves appear inside all *extended* bodies, be they solids, liquids, gases or plasmas. Inside fluid bodies, waves are *longitudinal*, meaning that the wave motion is in the same direction as the wave oscillation. Sound in air is an example of a longitudinal wave. Inside solid bodies, waves can also be *transverse*; in that case the wave oscillation is perpendicular to the travelling direction.

Waves appear also on *interfaces* between bodies: water–air interfaces are a well-known case. Even a saltwater–freshwater interface, so-called *dead water*, shows waves: they can appear even if the upper surface of the water is immobile. Any flight in an aeroplane provides an opportunity to study the regular cloud arrangements on the interface between warm and cold air layers in the atmosphere. Seismic waves travelling along the boundary between the sea floor and the sea water are also well-known. General surface waves are usually neither longitudinal nor transverse, but of a mixed type.

On water surfaces, one classifies waves according to the force that restores the plane surface. The first type, *surface tension waves*, plays a role on scales up to a few centimetres. At longer scales, gravity takes over as the main restoring force and one speaks of *gravity*



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 36 Some wave velocities

Wave	Velocity
Tsunami	around 0.2 km/s
Sound in most gases	0.3 ± 0.1 km/s
Sound in air at 273 K	0.331 km/s
Sound in air at 293 K	0.343 km/s
Sound in helium at 293 K	0.983 km/s
Sound in most liquids	1.2 ± 0.2 km/s
Sound in water at 273 K	1.402 km/s
Sound in water at 293 K	1.482 km/s
Sound in sea water at 298 K	1.531 km/s
Sound in gold	4.5 km/s
Sound in steel	5.8 to 5.960 km/s
Sound in granite	5.8 km/s
Sound in glass (longitudinal)	4 to 5.9 km/s
Sound in beryllium (longitudinal)	12.8 km/s
Sound in boron	up to 15 km/s
Sound in diamond	up to 18 km/s
Sound in fullerene (C_{60})	up to 26 km/s
Plasma wave velocity in InGaAs	600 km/s
Light in vacuum	$2.998 \cdot 10^8$ m/s

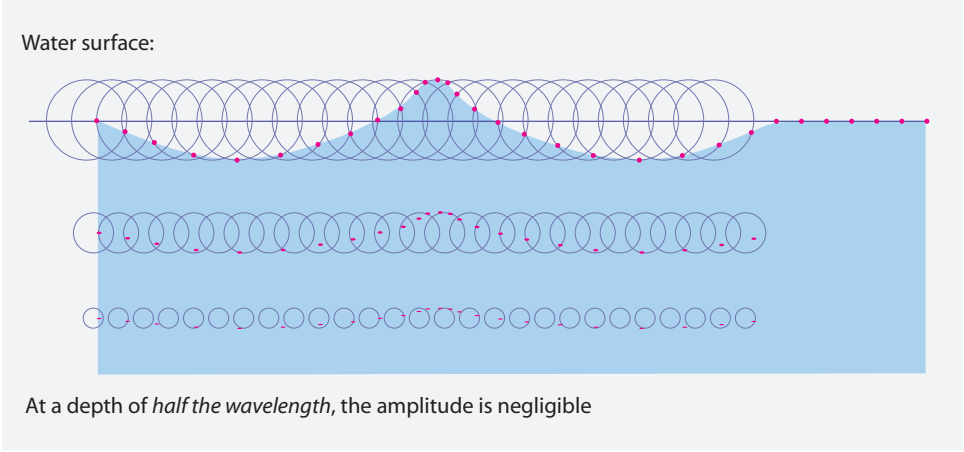


FIGURE 150 The formation of the shape of gravity waves on water from the circular motion of the water

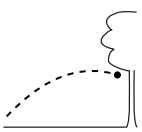
waves. This is the type we focus on here. Gravity waves in water, in contrast to surface tension waves, are not sine waves. This is because of the special way the water moves in such a wave. As shown in Figure 150, the surface water for a (short) water wave moves in circles; this leads to the typical, asymmetrical wave shape with short sharp crests and long

Page 228



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

shallow troughs. (As long as there is no wind and the floor below the water is horizontal, the waves are also symmetric under front-to-back reflection.)

For water gravity waves, as for many other waves, the speed depends on the wavelength. Indeed, the speed c of water waves depends on the wavelength λ and on the depth of the water d in the following way:

$$c = \sqrt{\frac{g\lambda}{2\pi} \tanh \frac{2\pi d}{\lambda}} \ , \tag{83}$$

where g is the acceleration due to gravity (and an amplitude much smaller than the wavelength is assumed). The formula shows two limiting regimes. First, so-called *short* or *deep waves* appear when the water depth is larger than half the wavelength; for deep waves, the phase velocity is $c \approx \sqrt{g\lambda/2\pi}$, thus wavelength dependent, and the group velocity is about half the phase velocity. Shorter deep waves are thus slower. Secondly, *shallow* or *long waves* appear when the depth is less than 5% of the wavelength; in this case, $c \approx \sqrt{gd}$, there is no dispersion, and the group velocity is about the same as the phase velocity. The most impressive shallow waves are tsunamis, the large waves triggered by submarine earthquakes. (The Japanese name is composed of *tsu*, meaning harbour, and *nami*, meaning wave.) Since tsunamis are shallow waves, they show little dispersion and thus travel over long distances; they can go round the Earth several times. Typical oscillation times are between 6 and 60 minutes, giving wavelengths between 70 and 700 km and speeds in the open sea of 200 to 250 m/s, similar to that of a jet plane. Their amplitude on the open sea is often of the order of 10 cm; however, the amplitude scales with depth d as $1/d^4$ and heights up to 40 m have been measured at the shore. This was the order of magnitude of the large and disastrous tsunami observed in the Indian Ocean on 26 December 2004.

Challenge 431 e

Waves can also exist in empty space. Both light and gravity waves are examples. The exploration of electromagnetism and relativity will tell us more about their properties.

Any study of motion must include the study of wave motion. We know from experience that waves can hit or even damage targets; thus every wave carries energy and momentum, even though (on average) no matter moves along the wave propagation direction. The *energy* E of a wave is the sum of its kinetic and potential energy. The kinetic energy (density) depends on the temporal change of the displacement u at a given spot: rapidly changing waves carry a larger kinetic energy. The potential energy (density) depends on the gradient of the displacement, i.e., on its spatial change: steep waves carry a larger potential energy than shallow ones. (Can you explain why the potential energy does not depend on the displacement itself?) For harmonic waves propagating along the direction z, each type of energy is proportional to the square of its respective displacement change:

Challenge 432 s

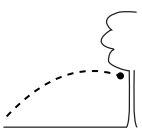
Ref. 179

$$E \sim (\frac{\partial u}{\partial t})^2 + v^2 (\frac{\partial u}{\partial z})^2 \ . \tag{84}$$

How is the energy density related to the frequency?

Challenge 433 ny

The *momentum* of a wave is directed along the direction of wave propagation. The momentum value depends on both the temporal and the spatial change of displacement



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

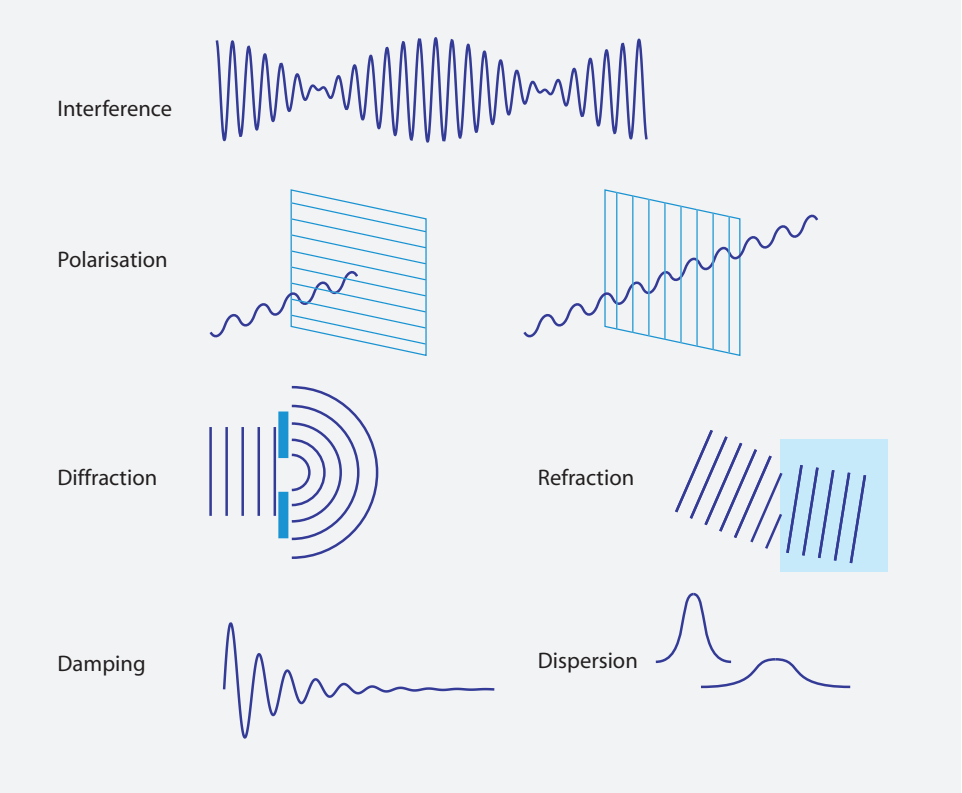


FIGURE 151 The six main properties of the motion of waves

u. For harmonic waves, the momentum (density) P is proportional to the product of these two quantities:

$$P_z \sim \frac{\partial u}{\partial t}\frac{\partial u}{\partial z} \,. \tag{85}$$

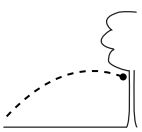
When two linear wave trains collide or interfere, the total momentum is conserved throughout the collision. An important consequence of momentum conservation is that waves that are reflected by an obstacle do so with an outgoing angle equal to minus the infalling angle. What happens to the phase?

Challenge 434 s

In summary, waves, like moving bodies, carry energy and momentum. In simple terms, if you shout against a wall, the wall is hit. This hit, for example, can start avalanches on snowy mountain slopes. In the same way, waves, like bodies, can carry also angular momentum. (What type of wave is necessary for this to be possible?) However, we can distinguish six main properties that set the motion of waves apart from the motion of bodies.

Challenge 435 ny

— Waves can add up or cancel each other out; thus they can interpenetrate each other. These effects, called *superposition* and *interference*, are strongly tied to the linearity of most waves.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

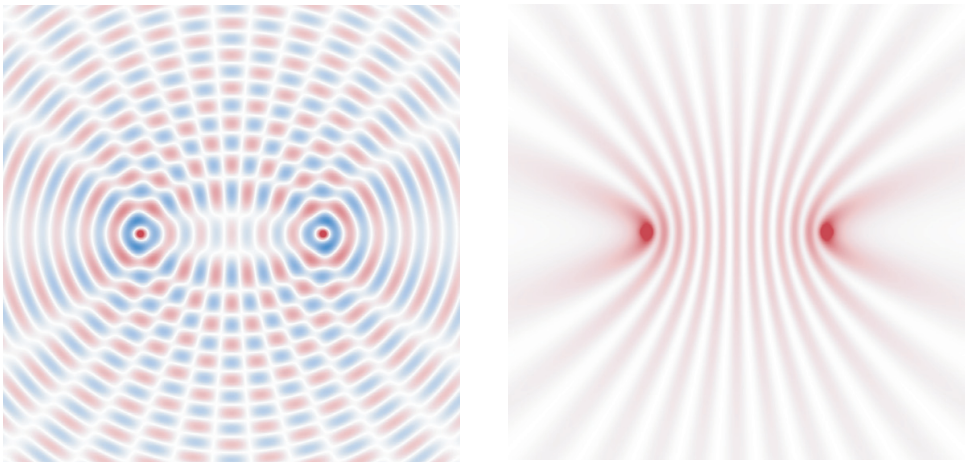


FIGURE 152 Interference of two circular or spherical waves emitted in phase: a snapshot of the amplitude (left), most useful to describe observations of water waves, and the distribution of the time-averaged intensity (right), most useful to describe interference of light waves (© Rüdiger Paschotta)

— Transverse waves in three dimensions can oscillate in different directions: they show *polarization*.
— Waves, such as sound, can go around corners. This is called *diffraction*.
— Waves change direction when they change medium. This is called *refraction*.
— Waves can have a frequency-dependent propagation speed. This is called *dispersion*.
— Often, the wave amplitude decreases over time: waves show *damping*.

Material bodies in everyday life do not behave in these ways when they move. These six wave effects appear because wave motion is the motion of *extended* entities. The famous debate whether electrons or light are waves or particles thus requires us to check whether these effects specific to waves can be observed or not. This is one topic of quantum theory. Before we study it, can you give an example of an observation that implies that a motion surely cannot be a wave?

Challenge 436 s

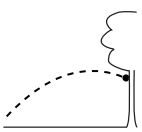
As a result of having a frequency f and a propagation velocity v, all sine waves are characterized by the distance λ between two neighbouring wave crests: this distance is called the wavelength. All waves obey the basic relation

$$\lambda f = v \,. \tag{86}$$

In many cases the wave velocity v depends on the wavelength of the wave. For example, this is the case for water waves. This change of speed with wavelength is called *dispersion*. In contrast, the speed of sound in air does not depend on the wavelength (to a high degree of accuracy). Sound in air shows almost no dispersion. Indeed, if there were dispersion for sound, we could not understand each other's speech at larger distances.

In everyday life we do not experience light as a wave, because the wavelength is only around one two-thousandth of a millimetre. But light shows all six effects typical of wave motion. A rainbow, for example, can only be understood fully when the last five wave

Page 723



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

effects are taken into account. Diffraction and interference can even be observed with your fingers only. Can you tell how? Challenge 437 s

Like every anharmonic oscillation, every anharmonic wave can be decomposed into sine waves. Figure 149 gives examples. If the various sine waves contained in a disturbance propagate differently, the original wave will change in shape while it travels. That is the reason why an echo does not sound exactly like the original sound; for the same reason, a nearby thunder and a far-away one sound different.

All systems which oscillate also emit waves. Any radio or TV receiver contains oscillators. As a result, any such receiver is also a (weak) transmitter; indeed, in some countries the authorities search for people who listen to radio without permission listening to the radio waves emitted by these devices. Also, inside the human ear, numerous tiny structures, the hair cells, oscillate. As a result, the ear must also emit sound. This prediction, made in 1948 by Tommy Gold, was confirmed only in 1979 by David Kemp. These so-called *otoacoustic emissions* can be detected with sensitive microphones; they are presently being studied in order to unravel the still unknown workings of the ear and in order to diagnose various ear illnesses without the need for surgery. Ref. 180

Since any travelling disturbance can be decomposed into sine waves, the term 'wave' is used by physicists for all travelling disturbances, whether they look like sine waves or not. In fact, the disturbances do not even have to be travelling. Take a standing wave: is it a wave or an oscillation? Standing waves do not travel; they are oscillations. But a standing wave can be seen as the superposition of two waves travelling in opposite directions. Since all oscillations are standing waves (can you confirm this?), we can say that in fact, all oscillations are special forms of waves. Challenge 438 ny

The most important travelling disturbances are those that are localized. Figure 149 shows an example of a localized wave group or pulse, together with its decomposition into harmonic waves. Wave groups are extensively used to talk and as signals for communication.

Why can we talk to each other? – Huygens' principle

The properties of our environment often disclose their full importance only when we ask simple questions. Why can we use the radio? Why can we talk on mobile phones? Why can we listen to each other? It turns out that a central part of the answer to these questions is that the space we live has an *odd* numbers of dimensions.

In spaces of *even* dimension, it is impossible to talk, because messages do not stop. This is an important result which is easily checked by throwing a stone into a lake: even after the stone has disappeared, waves are still emitted from the point at which it entered the water. Yet, when we stop talking, no waves are emitted any more. Waves in two and three dimensions thus behave differently.

In three dimensions, it is possible to say that the propagation of a wave happens in the following way: Every point on a wave front (of light or of sound) can be regarded as the source of secondary waves; the surface that is formed by the envelope of all the secondary waves determines the future position of the wave front. The idea is illustrated in Figure 153. It can be used to describe, without mathematics, the propagation of waves, their reflection, their refraction, and, with an extension due to Augustin Fresnel, their diffraction. (Try!) Challenge 439 e

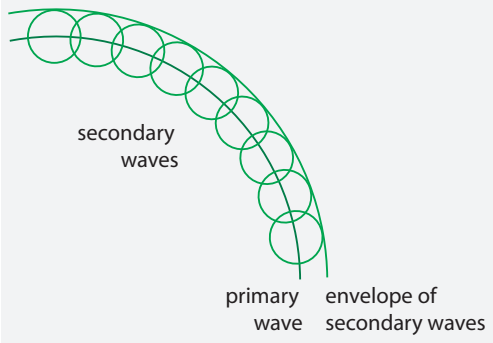

FIGURE 153 Wave propagation as a consequence of Huygens' principle

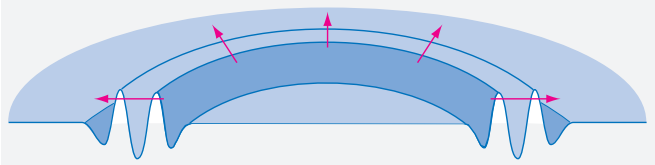

FIGURE 154 An impossible water wave: the centre is never flat

This idea was first proposed by Christiaan Huygens in 1678 and is called *Huygens' principle*. Almost two hundred years later, Gustav Kirchoff showed that the principle is a consequence of the wave equation in three dimensions, and thus, in the case of light, a consequence of Maxwell's field equations.

But the description of wave fronts as envelopes of secondary waves has an important limitation. It is not correct in two dimensions (even though Figure 153 is two-dimensional!). In particular, it does not apply to water waves. Water wave propagation *cannot* be calculated in this way in an exact manner. (It is only possible if the situation is limited to a waves of a single frequency.) It turns out that for water waves, secondary waves do not only depend on the wave front of the primary waves, but depend also on their interior. The reason is that in two (and other even) dimensions, waves of different frequency necessarily have different speeds. And a stone falling into water generates waves of many frequencies. In contrast, in three (and larger odd) dimensions, waves of all frequencies have the same speed.

We can also say that Huygens' principle holds if the wave equation is solved by a circular wave leaving no amplitude behind it. Mathematicians translate this by requiring that the evolving delta function $\delta(c^2t^2 - r^2)$ satisfies the wave equation, i.e., that $\partial_t^2\delta = c^2\Delta\delta$. The delta function is that strange 'function' which is zero everywhere except at the origin, where it is infinite. A few more properties describe the precise way in which this happens.* It turns out that the delta function is a solution of the wave equation only if the space dimension is odd and at least three. In other words, while a spherical wave pulse is possible, a circular pulse is not: there is no way to keep the centre of an expanding wave quiet. (See Figure 154.) That is exactly what the stone experiment shows. You can try to produce a circular pulse (a wave that has only a few crests) the next time you

* The main property is $\int \delta x \, dx = 1$. In mathematically precise terms, the delta 'function' is a distribution.

are in the bathroom or near a lake: you will not succeed.

In summary, the reason a room gets dark when we switch off the light, is that we live in a space with a number of dimensions which is odd and larger than one.

Why is music so beautiful?

Music works because it connect to emotions. And it does so, among others, by reminding us of the sounds (and emotions connected to them) that we experienced before birth. Percussion instruments remind us of the heart beat of our mother and ourselves, cord and wind instruments remind us of all the voices we heard back then. Musical instruments are especially beautiful if they are driven and modulated by the body of the player. All classical instruments are optimized to allow this modulation and the ability to express emotions in this way.

The connection between the musician and the instrument is most intense for the human voice; the next approximation are the wind instruments. In all these cases, the breath of the singer or player does two things: it provides the energy for the sound and it gives an input for the feedback loop that sets the pitch. While singing, the air passes the vocal cords. The rapid air flow reduces the air pressure, which attracts the cords to each other and thus reduces the cross section for the air flow. (This pressure reduction is described Page 260 by the Bernoulli equation, as explained below.) As a result of the smaller cross section, the airflow is reduced, the pressure rises again, and the vocal cords open up again. This leads to larger airflow, and the circle starts again. The change between larger and smaller cord distance repeats so rapidly that sound is produced; the sound is then amplified in the mouth by the resonances that depend on the shape of the oral cavity.

Ref. 181 In *reed instruments*, such as the clarinet, the reed has the role of the vocal cords, and the pipe and the mechanisms have the role of the mouth. In *brass instruments*, such as the trombone, the lips play the role of the reed. In *airflow instruments*, such as the flute, the feedback loop is due to another effect: at the sound-producing edge, the airflow is deflected by the sound itself.

The second reason that music is beautiful is due to the way the frequencies of the notes are selected. Certain frequencies sound agreeable to the ear when they are played together or closely after each other; other produce a sense of tension. Already the ancient Greek had discovered that these sensations depend exclusively on the on the *ratio* of the frequencies, or as musician say, on the *interval* between the pitches.

More specifically, a frequency ratio of 2 – musicians call the interval an *octave* – is the most agreeable consonance. A ratio of 3/2 (called perfect fifth) is the next most agreeable, followed by the ratio 4/3 (a perfect fourth), the ratio 5/4 (a major third) and the ratio 6/5 (a minor third). The choice of the first third in a scale has an important effect on the average emotions expressed by the music and is therefore also taken over in the name of the scale. Songs in C major generally have a more happy tune, whereas songs in A minor tend to sound sadder.

The least agreeable frequency ratios, the dissonances, are the *tritone* (7/5, also called *augmented fourth* or *diminished fifth*) and, to a lesser extent, the major and minor seventh (15/8 and 9/5). The false quint is used for the siren in German red cross vans. Long sequences of dissonances have the effect to induce trance; they are common in Balinese music and in jazz.

equal intonation or *well-tempered intonation*, contains approximations to all the mentioned intervals; the approximations have the advantage that they allow the *transposition* of music to lower or higher notes. This is not possible with the ideal, so-called *just intonation*.

Ref. 182

The next time you sing a song that you like, you might try to determine whether you use just or equal intonation – or a different intonation altogether. Different people have different tastes and habits.

Challenge 440 e

Signals

A signal is the transport of information. Every signal, including those from Table 37, is motion of energy. Signals can be either objects or waves. A thrown stone can be a signal, as can a whistle. Waves are a more practical form of communication because they do not require transport of matter: it is easier to use electricity in a telephone wire to transport a statement than to send a messenger. Indeed, most modern technological advances can be traced to the separation between signal and matter transport. Instead of transporting an

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

orchestra to transmit music, we can send radio signals. Instead of sending paper letters we write email messages. Instead of going to the library we browse the internet.

The greatest advances in communication have resulted from the use of signals to transport large amounts of energy. That is what electric cables do: they transport energy without transporting any (noticeable) matter. We do not need to attach our kitchen machines to the power station: we can get the energy via a copper wire.

For all these reasons, the term 'signal' is often meant to imply waves only. Voice, sound, electric signals, radio and light signals are the most common examples of wave signals.

Signals are characterized by their speed and their information content. Both quantities turn out to be limited. The limit on speed is the central topic of the theory of special relativity.

Page 401

A simple limit on information content can be expressed when noting that the information flow is given by the detailed shape of the signal. The shape is characterized by a frequency (or wavelength) and a position in time (or space). For every signal – and every wave – there is a relation between the time-of-arrival error Δt and the angular frequency error $\Delta\omega$:

$$\Delta t \, \Delta\omega \geqslant \frac{1}{2} \,. \tag{87}$$

This time–frequency indeterminacy relation expresses that, in a signal, it is impossible to specify both the time of arrival and the frequency with full precision. The two errors are (within a numerical factor) the inverse of each other. (One also says that the time-bandwidth product is always larger than $1/4\pi$.) The limitation appears because on one hand one needs a wave as similar as possible to a sine wave in order to precisely determine the frequency, but on the other hand one needs a signal as narrow as possible to precisely determine its time of arrival. The contrast in the two requirements leads to the limit. The indeterminacy relation is thus a feature of every wave phenomenon. You might want to test this relation with any wave in your environment.

Challenge 441 e

Similarly, there is a relation between the position error Δx and the wave vector error $\Delta k = 2\pi/\Delta\lambda$ of a signal:

$$\Delta x \, \Delta k \geqslant \frac{1}{2} \,. \tag{88}$$

Like the previous case, also this indeterminacy relation expresses that it is impossible to specify both the position of a signal and its wavelength with full precision. Also this position–wave-vector indeterminacy relation is a feature of any wave phenomenon.

Every indeterminacy relation is the consequence of a smallest entity. In the case of waves, the smallest entity of the phenomenon is the period (or cycle, as it used to be called). Whenever there is a smallest unit in a natural phenomenon, an indeterminacy relation results. We will encounter other indeterminacy relations both in relativity and in quantum theory. As we will find out, they are due to smallest entities as well.

Whenever signals are sent, their content can be lost. Each of the six characteristics of waves listed on page 232 can lead to content degradation. Can you provide an example for each case? The energy, the momentum and all other conserved properties of signals are never lost, of course. The disappearance of signals is akin to the disappearance of motion. When motion disappears by friction, it only seems to disappear, and is in fact

Challenge 442 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

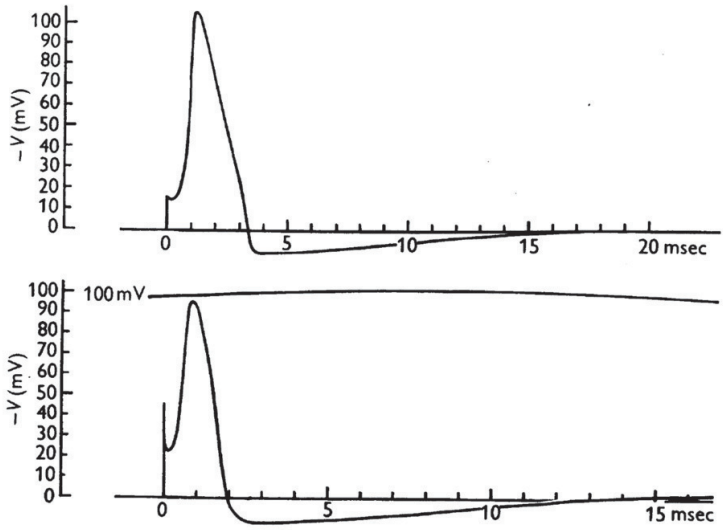

Fig. 13. Upper curve: solution of eqn. (26) for initial depolarization of 15 mV, calculated for 6° C. Lower curve: tracing of membrane action potential recorded at 9·1° C (axon 14). The vertical scales are the same in both curves (apart from curvature in the lower record). The horizontal scales differ by a factor appropriate to the temperature difference.

FIGURE 156 The electrical signals calculated (above) and measured (below) in a nerve, following Hodgkin and Huxley

transformed into heat. Similarly, when a signal disappears, it only seems to disappear, and is in fact transformed into noise. *(Physical) noise* is a collection of numerous disordered signals, in the same way that heat is a collection of numerous disordered movements.

All signal propagation is described by a wave equation. A famous example is the set
Ref. 183 of equations found by Hodgkin and Huxley. It is a realistic approximation for the behaviour of electrical potential in nerves. Using facts about the behaviour of potassium and sodium ions, they found an elaborate equation that describes the voltage V in nerves, and thus the way the signals are propagated. The equation accurately describes the characteristic voltage spikes measured in nerves, shown in Figure 156. The figure clearly shows that these waves differ from sine waves: they are not harmonic. Anharmonicity is one result of nonlinearity. But nonlinearity can lead to even stronger effects.

Solitary waves and solitons

In August 1834, the Scottish engineer John Scott Russell (1808–1882) recorded a strange observation in a water canal in the countryside near Edinburgh. When a boat pulled through the channel was suddenly stopped, a strange water wave departed from it. It consisted of a *single* crest, about 10 m long and 0.5 m high, moving at about 4 m/s. He followed that crest, shown in a reconstruction in Figure 157, with his horse for several kilometres: the wave died out only very slowly. Russell did not observe any dispersion, as is usual in water waves: the width of the crest remained constant. Russell then started pro-
Ref. 184 ducing such waves in his laboratory, and extensively studied their properties. He showed

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 157 A solitary water wave followed by a motor boat, reconstructing the discovery by Scott Russel (© Dugald Duncan)

that the speed depended on the amplitude, in contrast to linear, harmonic waves. He also found that the depth d of the water canal was an important parameter. In fact, the speed v, the amplitude A and the width L of these single-crested waves are related by

$$v = \sqrt{gd}\left(1 + \frac{A}{2d}\right) \quad \text{and} \quad L = \sqrt{\frac{4d^3}{3A}} \,. \tag{89}$$

As shown by these expressions, and noted by Russell, high waves are narrow and fast, whereas shallow waves are slow and wide. The shape of the waves is fixed during their motion. Today, these and all other stable waves with a single crest are called *solitary waves*. They appear only where the dispersion and the nonlinearity of the system exactly compensate for each other. Russell also noted that the solitary waves in water channels can cross each other unchanged, even when travelling in opposite directions; solitary waves with this property are called *solitons*. In short, solitons are stable against encounters, as shown in Figure 158, whereas solitary waves in general are not.

Only sixty years later, in 1895, Korteweg and de Vries found out that solitary waves in water channels have a shape described by

$$u(x,t) = A \operatorname{sech}^2 \frac{x - vt}{L} \quad \text{where} \quad \operatorname{sech} x = \frac{2}{e^x + e^{-x}} \,, \tag{90}$$

and that the relation found by Russell was due to the wave equation

$$\frac{1}{\sqrt{gd}} \frac{\partial u}{\partial t} + \left(1 + \frac{3}{2d} u\right) \frac{\partial u}{\partial x} + \frac{d^2}{6} \frac{\partial^3 u}{\partial x^3} = 0 \,. \tag{91}$$

This equation for the elongation u is called the *Korteweg–de Vries equation* in their hon-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

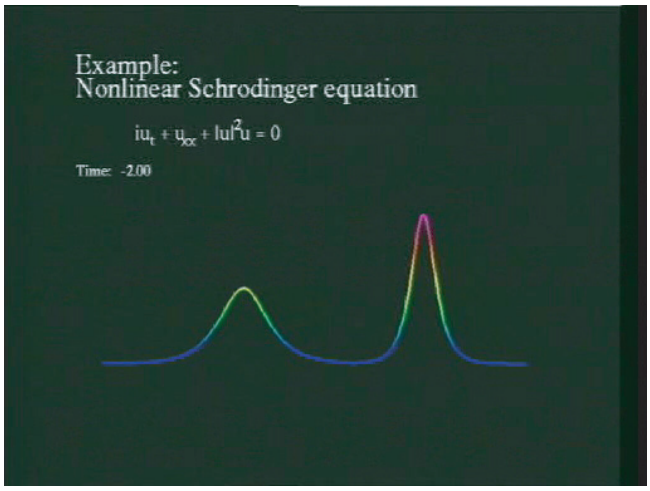

FIGURE 158 Solitons are stable against encounters (QuickTime film © Jarmo Hietarinta)

our.* The surprising stability of the solitary solutions is due to the opposite effect of the two terms that distinguish the equation from linear wave equations: for the solitary solutions, the nonlinear term precisely compensates for the dispersion induced by the third-derivative term.

For many decades such solitary waves were seen as mathematical and physical curiosities. But almost a hundred years later it became clear that the Korteweg–de Vries equation is a universal model for weakly nonlinear waves in the weak dispersion regime, and thus of basic importance. This conclusion was triggered by Kruskal and Zabusky, who in 1965 proved mathematically that the solutions (90) are unchanged in collisions. Ref. 185 This discovery prompted them to introduce the term *soliton*. These solutions do indeed interpenetrate one another without changing velocity or shape: a collision only produces a small positional shift for each pulse.

Solitary waves play a role in many examples of fluid flows. They are found in ocean currents; and even the red spot on Jupiter, which was a steady feature of Jupiter photographs for many centuries, is an example.

Solitary waves also appear when extremely high-intensity sound is generated in solids. Ref. 186 In these cases, they can lead to sound pulses of only a few nanometres in length. Solitary light pulses are also used inside certain optical communication fibres, where the lack of dispersion allows higher data transmission rates than are achievable with usual light Ref. 184 pulses.

Towards the end of the twentieth century a second wave of interest in the mathematics of solitons arose, when quantum theorists became interested in them. The reason is simple but deep: a soliton is a 'middle thing' between a particle and a wave; it has features of both concepts. For this reason, solitons are seen as candidates for the description of

* The equation can be simplified by transforming the variable u; most concisely, it can be rewritten as $u_t + u_{xxx} = 6uu_x$. As long as the solutions are sech functions, this and other transformed versions of the equation are known by the same name.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

elementary particles.

Curiosities and fun challenges about waves and extended bodies

> Society is a wave. The wave moves onward, but the water of which it is composed does not.
> Ralph Waldo Emerson, *Self-Reliance*.

When the frequency of a tone is doubled, one says that the tone is higher by an octave. Two tones that differ by an octave, when played together, sound pleasant to the ear. Two other agreeable frequency ratios – or 'intervals', as musicians say – are quarts and quints. Challenge 443 e What are the corresponding frequency ratios? (Note: the answer was one of the oldest discoveries in physics and perception research; it is attributed to Pythagoras, around 500 BCE.)

* *

An orchestra is playing music in a large hall. At a distance of 30 m, somebody is listening to the music. At a distance of 3000 km, another person is listening to the music via the Challenge 444 s radio. Who hears the music first?

* *

What is the period of a simple pendulum, i.e., a mass m attached to a massless string of Challenge 445 ny length l? What is the period if the string is much longer than the radius of the Earth?

* *

What path is followed by a body that moves without friction on a plane, but that is at-Challenge 446 s tached by a spring to a fixed point on the plane?

* *

A device that shows how rotation and oscillation are linked is the alarm *siren*. Find out Challenge 447 e how it works, and build one yourself.

* *

Light is a wave, as we will discover later on. As a result, light reaching the Earth from space is refracted when it enters the atmosphere. Can you confirm that as a result, stars Challenge 448 e appear somewhat higher in the night sky than they really are?

* *

What are the highest sea waves? This question has been researched systematically only Ref. 187 recently, using satellites. The surprising result is that sea waves with a height of 25 m and more are *common*: there are a few such waves on the oceans at any given time. This result confirms the rare stories of experienced ship captains and explains many otherwise ship sinkings.

Surfers may thus get many chances to ride 30 m waves. (The record is just below this height.) But maybe the most impressive waves to surf are those of the Pororoca, a series of 4 m waves that move from the sea into the Amazon River every spring, against the flow of the river. These waves can be surfed for tens of kilometres.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

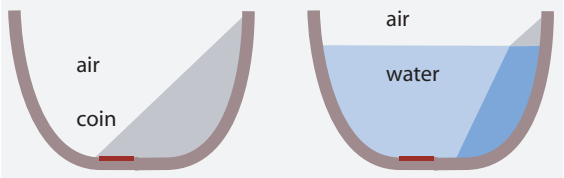

FIGURE 159 Shadows show the refraction of light

* *

All waves are damped, eventually. This effect is often frequency-dependent. Can you pro-
Challenge 449 s vide a confirmation of this dependence in the case of sound in air?

* *

When you make a hole with a needle in black paper, the hole can be used as a magnifying
Challenge 450 e lens. (Try it.) Diffraction is responsible for the lens effect. By the way, the diffraction of light by holes was noted already by Francesco Grimaldi in the seventeenth century; he correctly deduced that light is a wave. His observations were later discussed by Newton, who wrongly dismissed them.

* *

Put an empty cup near a lamp, in such a way that the bottom of the cup remains in the shadow. When you fill the cup with water, some of the bottom will be lit, because of the refraction of the light from the lamp. The same effect is at the basis of instruments such as the telescope.
Page 739

* *

Challenge 451 s Are water waves transverse or longitudinal?

* *

The speed of water waves limits the speeds of ships. A surface ship cannot travel (much) faster than about $v_{\text{crit}} = \sqrt{0.16gl}$, where $g = 9.8\,\text{m/s}^2$, l is its length, and 0.16 is a number determined experimentally, called the *critical Froude number*. This relation is valid for all vessels, from large tankers ($l = 100\,\text{m}$ gives $v_{\text{crit}} = 13\,\text{m/s}$) down to ducks ($l = 0.3\,\text{m}$ gives $v_{\text{crit}} = 0.7\,\text{m/s}$). The critical speed is that of a wave with the same wavelength as the ship. In fact, moving a ship at higher speeds than the critical value is possible, but requires much more energy. (A higher speed is also possible if the ship surfs on a wave.) How far
Challenge 452 s away is the crawl *olympic swimming* record from the critical value?

Most water animals and ships are faster when they swim below the surface – where the limit due to surface waves does not exist – than when they swim on the surface. For example, ducks can swim three times as fast under water than on the surface.

* *

The group velocity of water waves (in deep water) is less than the velocity of the individual wave crests, the so-called *phase velocity*. As a result, when a group of wave crests travels, within the group the crests move from the back to the front: they appear at the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

back, travel forward and then die out at the front. The group velocity of water waves is lower than its phase velocity.

* *

One can hear the distant sea or a distant highway more clearly in the evening than in the morning. This is an effect of refraction. Sound speed decreases with temperature. In the evening, the ground cools more quickly than the air above. As a result, sound leaving the ground and travelling upwards is refracted downwards, leading to the long hearing distance. In the morning, usually the air is cold above and warm below. Sound is refracted upwards, and distant sound does not reach a listener on the ground. Refraction thus implies that mornings are quiet, and that one can hear more distant sounds in the evenings. Elephants use the sound situation during evenings to communicate over distances of more than 10 km. (They also use sound waves in the ground to communicate, but that is another story.)

* *

Refraction also implies that there is a sound channel in the ocean, and in the atmosphere. Sound speed decreases with temperature, and increases with pressure. At an ocean depth of 1 km, or at an atmospheric height of 13 to 17 km (that is at the top of the tallest cumulonimbus clouds or equivalently, at the middle of the ozone layer) sound has *minimal* speed. As a result, sound that starts from that level and tries to leave is channelled back to it. Whales use the sound channel to communicate with each other with beautiful songs; one can find recordings of these songs on the internet. The military successfully uses microphones placed at the sound channel in the ocean to locate submarines, and microphones on balloons in the atmospheric channel to listen for nuclear explosions. (In fact, sound experiments conducted by the military are the main reason why whales are deafened and lose their orientation, stranding on the shores. Similar experiments in the air with high-altitude balloons are often mistaken for flying saucers, as in the famous Roswell incident.)

Challenge 453 e

Ref. 188

* *

Ref. 189 Also small animals communicate by sound waves. In 2003, it was found that herring communicate using noises they produce when farting. When they pass wind, the gas creates a ticking sound whose frequency spectrum reaches up to 20 kHz. One can even listen to recordings of this sound on the internet. The details of the communication, such as the differences between males and females, are still being investigated. It is possible that the sounds may also be used by predators to detect herring, and they might even be used by future fishing vessels.

* *

On windy seas, the white wave crests have several important effects. The noise stems from tiny exploding and imploding water bubbles. The noise of waves on the open sea is thus the superposition of many small explosions. At the same time, white crests are the events where the seas absorb carbon dioxide from the atmosphere, and thus reduce global warming.

Challenge 454 s Why are there many small holes in the ceilings of many office rooms?

* *

Challenge 455 ny Which quantity determines the wavelength of water waves emitted when a stone is thrown into a pond?

* *

Ref. 2 Yakov Perelman lists the following four problems in his delightful physics problem book.

Challenge 456 s (1) A stone falling into a lake produces circular waves. What is the shape of waves produced by a stone falling into a river, where the water flows?

Challenge 457 s (2) It is possible to build a lens for sound, in the same way as it is possible to build lenses for light. What would such a lens look like?

Challenge 458 ny (3) What is the sound heard inside a shell?

Challenge 459 s (4) Light takes about eight minutes to travel from the Sun to the Earth. What consequence does this have for the timing of sunrise?

* *

Challenge 460 s Can you deduce how a Rubik's Cube is built? And its generalizations to higher numbers of segments? Is there a limit to the number of segments? These puzzles are even tougher than the search for a rearrangement of the cube.

* *

Challenge 461 ny Typically, sound of a talking person produces a pressure variation of 20 mPa on the ear. How is this determined?

The ear is indeed a sensitive device. It is now known that most cases of sea mammals, like whales, swimming onto the shore are due to ear problems: usually some military device (either sonar signals or explosions) has destroyed their ear so that they became deaf and lose orientation.

* *

Infrasound, inaudible sound below 20 Hz, is a modern topic of research. In nature, infrasound is emitted by earthquakes, volcanic eruptions, wind, thunder, waterfalls, falling meteorites and the surf. Glacier motion, seaquakes, avalanches and geomagnetic storms Ref. 190 also emit infrasound. Human sources include missile launches, traffic, fuel engines and air compressors.

It is known that high intensities of infrasound lead to vomiting or disturbances of the sense of equilibrium (140 dB or more for 2 minutes), and even to death (170 dB for 10 minutes). The effects of lower intensities on human health are not yet known.

Infrasound can travel several times around the world before dying down, as the explosion of the Krakatoa volcano showed in 1883. With modern infrasound detectors, sea surf can be detected hundreds of kilometres away. Sea surf leads to a constant 'hum' of the Earth's crust at frequencies between 3 and 7 mHz. The *Global infrasound Network* uses infrasound to detect nuclear weapon tests, earthquakes and volcanic eruptions, and can count meteorites. Only very rarely can meteorites be heard with the human ear.

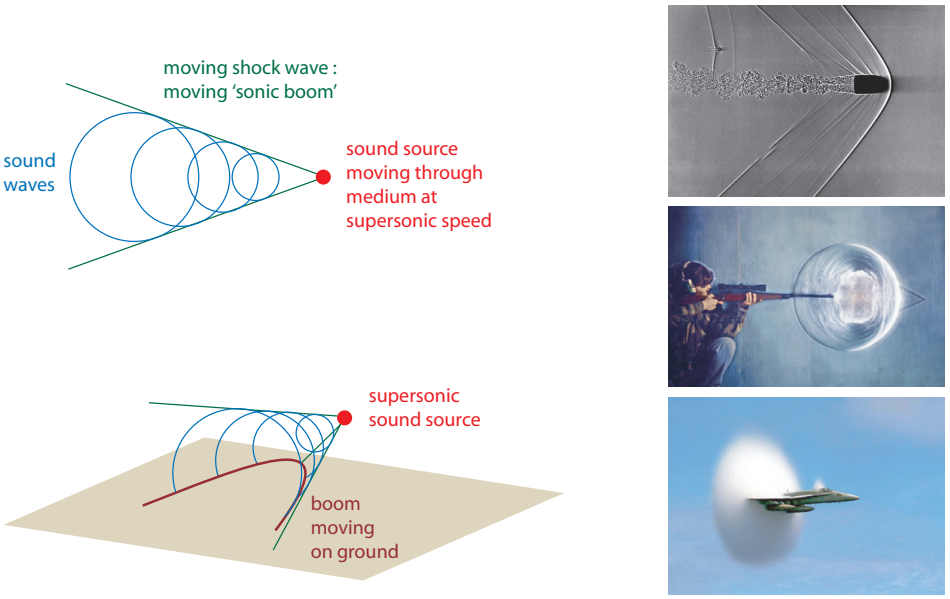

FIGURE 160 The shock wave created by a body in supersonic motion leads to a 'sonic boom' that moves through the air; it can be made visible by Schlieren photography or by water condensation (photo © Andrew Davidhazy, Gary Settles, NASA)

* *

The method used to deduce the sine waves contained in a signal, as shown in Figure 149, is called the Fourier transformation. It is of importance throughout science and technology. In the 1980s, an interesting generalization became popular, called the *wavelet transformation*. In contrast to Fourier transformations, wavelet transformations allow us to localize signals in time. Wavelet transformations are used to compress digitally stored images in an efficient way, to diagnose aeroplane turbine problems, and in many other applications. Ref. 191

A special type of waves appears in explosions and supersonic flight: *shock waves*. In a shock wave, the density or pressure of a gas changes abruptly, on distances of a few micrometers. Studying shock waves is a research field in itself; shock waves determine the flight of bullets, the snapping of whips and the effects of detonations.

Around a body moving with supersonic speed, the sound waves form a cone, as shown in Figure 160. When the cone passes an observer on the ground, the cone leads to a *sonic boom*. What is less well known is that the boom can be amplified. If an aeroplane *accelerates* through the sound barrier, certain observers at the ground will hear a superboom, because cones from various speeds can superpose at certain spots on the ground. A plane that performs certain manoeuvers, such as a curve at high speed, can even produce a superboom at a predefined spot on the ground. In contrast to normal sonic booms, superbooms can destroy windows, eardrums and lead to trauma, especially in children. Unfortunately, they are regularly produced on purpose by frustrated military pilots in various places of the world.

* *

Bats fly at night using *echolocation*. Dolphins also use it. Sonar, used by fishing vessels to look for fish, copies the system of dolphins. Less well known is that humans have the same ability. Have you ever tried to echolocate a wall in a completely dark room? You will be surprised at how easily this is possible. Just make a loud hissing or whistling noise that stops abruptly, and listen to the echo. You will be able to locate walls reliably.

Every soliton is a one-dimensional structure. Do two-dimensional analogues exist? This issue was open for many years. Finally, in 1988, Boiti, Leon, Martina and Pempinelli found that a certain evolution equation, the so-called Davey–Stewartson equation, can have solutions that are localized in two dimensions. These results were generalized by Fokas and Santini and further generalized by Hietarinta and Hirota. Such a solution is today called a *dromion*. Dromions are bumps that are localized in two dimensions and can move, without disappearing through diffusion, in non-linear systems. An example is shown in Figure 161. However, so far, no such solution has be observed in experiments; this is one of the most important experimental challenges left open in non-linear science.

Ref. 193

How does the tone produced by blowing over a bottle depend on the dimension? For bottles that are bulky, the frequency f, the so-called *cavity resonance*, is found to depend on the volume V of the bottle:

Ref. 194

$$f = \frac{c}{2\pi}\sqrt{\frac{A}{VL}} \quad \text{or} \quad f \sim \frac{1}{\sqrt{V}} \tag{92}$$

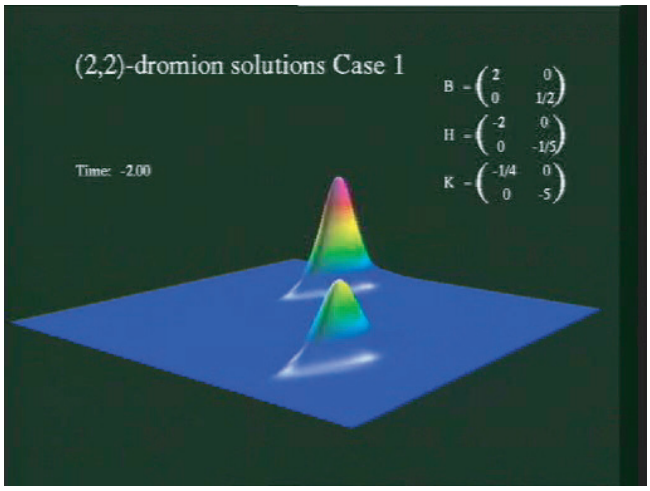

FIGURE 161 The calculated motion of a dromion across a two-dimensional substrate (QuickTime film © Jarmo Hietarinta)

where c is the speed of sound, A is the area of the opening, and L is the length of the neck of the bottle. Does the formula agree with your observations? Challenge 465 e

In fact, tone production is a complicated issue, and specialized books exist on the topic. For example, when overblowing, a saxophone produces a second harmonic, an octave, whereas a clarinet produces a third harmonic, a quint (more precisely, a twelfth). Why is this the case? The theory is complex, but the result simple: instruments whose cross-section increases along the tube, such as horns, trumpets, oboes or saxophones, overblow to octaves. For air instruments that have a (mostly) cylindrical tube, the effect of overblowing depends on the tone generation mechanism. Flutes overblow to the octave, but clarinets to the twelfth. Ref. 195

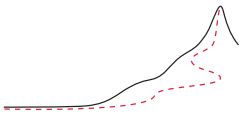
* *

Many acoustical systems do not only produce harmonics, but also subharmonics. There is a simple way to observe production of subharmonics: sing with your ears below water, in the bathtub. Depending on the air left in your ears, you can hear subharmonics of your own voice. The effect is quite special.

Summary on waves and oscillations

In nature, apart from the motion of bodies, we observe also the motion of signals, or waves. Waves have energy, momentum and angular momentum. They can interfere, diffract, refract, disperse, dampen out and, if transverse, can be polarized. Oscillations are a special case of waves.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 11

DO EXTENDED BODIES EXIST? – LIMITS OF CONTINUITY

We have just discussed the motion of extended bodies. We have seen that all extended bodies show wave motion. But are extended bodies found in nature? Strangely enough, this question has been one of the most intensely discussed questions in physics. Over the centuries, it has reappeared again and again, at each improvement of the description of motion; the answer has alternated between the affirmative and the negative. Many thinkers have been imprisoned, and many still are being persecuted, for giving answers that are not politically correct! In fact, the issue already arises in everyday life.

Mountains and fractals

Whenever we climb a mountain, we follow the outline of its shape. We usually describe this outline as a curved two-dimensional surface. But is this correct? There are alternative possibilities. The most popular is the idea that mountains are fractal surfaces. A *fractal* was defined by Benoît Mandelbrot as a set that is self-similar under a countable but in-
Page 58
finite number of magnification values.* We have already encountered fractal lines. An example of an algorithm for building a (random) fractal *surface* is shown on the right
Ref. 196
side of Figure 162. It produces shapes which look remarkably similar to real mountains. The results are so realistic that they are used in Hollywood films. If this description were correct, mountains would be extended, but not continuous.

But mountains could also be fractals of a different sort, as shown in the left side of Figure 162. Mountain surfaces could have an infinity of small and smaller holes. In fact, one could also imagine that mountains are described as three-dimensional versions of the left side of the figure. Mountains would then be some sort of mathematical Swiss cheese. Can you devise an experiment to decide whether fractals provide the correct
Challenge 466 s
description for mountains? To settle the issue, a chocolate bar can help.

Can a chocolate bar last forever?

> From a drop of water a logician could predict
> an Atlantic or a Niagara.
> Arthur Conan Doyle, *A Study in Scarlet*

Any child knows how to make a chocolate bar last forever: eat half the remainder every day. However, this method only works if matter is scale-invariant. In other words, the method only works if matter is either *fractal*, as it then would be scale-invariant for a

* For a definition of uncountability, see page 825.

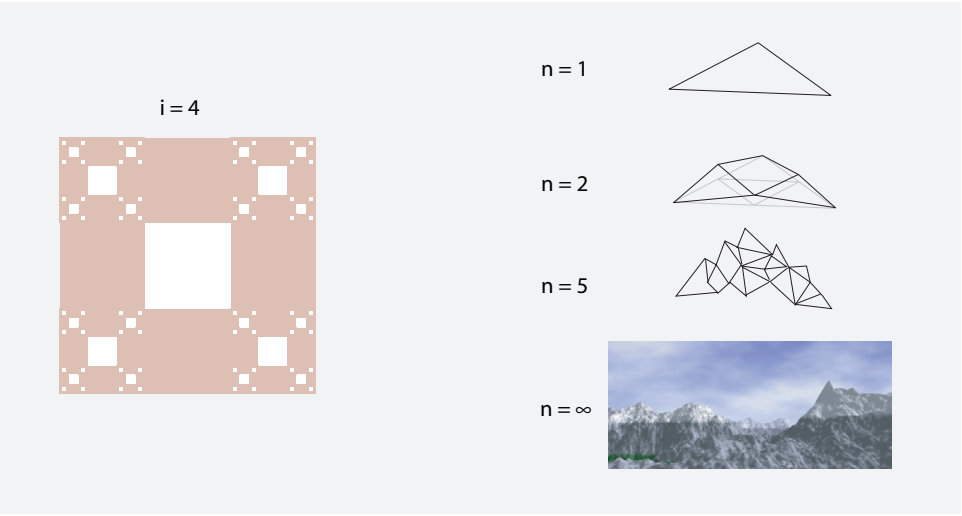

FIGURE 162 Floors (left) and mountains (right) could be fractals; for mountains this approximation is often used in computer graphics (image © Paul Martz)

discrete set of zoom factors, or *continuous*, in which case it would be scale-invariant for any zoom factor. Which case, if either, applies to nature?

Page 57

We have already encountered a fact making continuity a questionable assumption: continuity would allow us, as Banach and Tarski showed, to multiply food and any other matter by clever cutting and reassembling. Continuity would allow children to eat the *same* amount of chocolate every day, without ever buying a new bar. Matter is thus not continuous. Now, fractal chocolate is not ruled out in this way; but other experiments settle the question. Indeed, we note that melted materials do not take up much smaller volumes than solid ones. We also find that even under the highest pressures, materials do not shrink. Thus matter is not a fractal. What then is its structure?

To get an idea of the structure of matter we can take fluid chocolate, or even just some oil – which is the main ingredient of chocolate anyway – and spread it out over a large surface. For example, we can spread a drop of oil onto a pond on a day without rain or wind; it is not difficult to observe which parts of the water are covered by the oil and which are not. A small droplet of oil cannot cover a surface larger than – can you guess the value? Trying to spread the film further inevitably rips it apart. The child's method of prolonging chocolate thus does not work for ever: it comes to a sudden end. The oil experiment, which can even be conducted at home, shows that there is a *minimum* thickness of oil films, with a value of about 2 nm. The experiment shows that there is a smallest size in oil. Oil, and all matter, is made of tiny components. This confirms the observations made by Joseph Loschmidt* in 1865, who was the first person to measure

Challenge 467 s

* Joseph Loschmidt (b. 1821 Putschirn, d. 1895 Vienna) Austrian chemist and physicist. The oil experiment was popularized a few decades later, by Kelvin. It is often claimed that Benjamin Franklin was the first to conduct the oil experiment; that is wrong. Franklin did not measure the thickness, and did not even consider the question of the thickness. He did pour oil on water, but missed the most important conclusion that could be drawn from it. Even geniuses do not discover everything.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the size of the components of matter.

Loschmidt knew that the (dynamic) viscosity of a gas was given by $\eta = \rho l v/3$, where ρ is the density of the gas, v the average speed of the components and l their mean free path. With Avogadro's prediction (made in 1811 without specifying any value) that a volume V of any gas always contains the same number N of components, one also has $l = V/\sqrt{2\pi N\sigma^2}$, where σ is the cross-section of the components. (The cross-section is roughly the area of the shadow of an object.) Loschmidt then assumed that when the gas is liquefied, the volume of the liquid is the sum of the volumes of the particles. He then measured all the involved quantities and determined N. The modern value of N, called *Avogadro's number* or *Loschmidt's number*, is $6.02 \cdot 10^{23}$ particles in 22.4 l of any gas at standard conditions (today called 1 mol).

In 1865, it was not a surprise that matter was made of small components, as the existence of a smallest size – but not its value – had already been deduced by Galileo, when studying some other simple questions.

The case of Galileo Galilei

During his life, Galileo (1564–1642) was under attack for two reasons: because of his ideas about atoms, and because of his ideas on the motion of the Earth. * The discovery of the importance of both issues is the merit of the great historian Pietro Redondi, a collaborator of another great historian, Pierre Costabel. One of Redondi's research topics is the history of the dispute between the Jesuits, who at the time defended orthodox theology, and Galileo and the other scientists. In the 1980s, Redondi discovered a document of that time, an anonymous denunciation called G3, that allowed him to show that the condemnation of Galileo to life imprisonment for his views on the Earth's motion was organized by his friend the Pope to *protect* him from a sure condemnation to death over a different issue: atoms.

Galileo defended the view that since matter is not scale invariant, it must be made of 'atoms' or, as he called them, piccolissimi quanti – smallest quanta. This was and still is a heresy, because atoms of matter contradict the central Catholic idea that in the Eucharist the *sensible qualities* of bread and wine exist independently of their *substance*. The distinction between substance and sensible qualities, introduced by Thomas Aquinas, is essential to make sense of *transubstantiation*, the change of bread and wine into human flesh and blood, which is a central tenet of the Catholic faith. Indeed, a true Catholic is still not allowed to believe in atoms to the present day, because the idea that matter is made of atoms contradicts transubstantiation.

Ref. 197

In Galileo's days, church tribunals punished heresy, i.e., personal opinions deviating from orthodox theology, by the death sentence. Galileo's life was saved by the Pope by making sure that the issue of transubstantiation would not be topic of the trial, and by ensuring that the trial at the Inquisition be organized by a papal commission led by his nephew, Francesco Barberini. But the Pope also wanted Galileo to be punished, because

* To get a clear view of the matters of dispute in the case of Galileo, especially those of interest to physicists, the best text is the excellent book by Pietro Redondi, *Galileo eretico*, Einaudi, 1983, translated into English as *Galileo Heretic*, Princeton University Press, 1987. It is also available in many other languages; an updated edition that includes the newest discoveries appeared in 2004.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

he felt that his own ideas had been mocked in Galileo's book *Il Dialogo* and also because, under attack for his foreign policy, he was not able to ignore or suppress the issue.

As a result, in 1633 the seventy-year-old Galileo was condemned to a prison sentence, 'after invoking the name of Jesus Christ', for 'suspicion of heresy' (and thus not for heresy), Ref. 198 because he did not comply with an earlier promise not to teach that the Earth moves. Indeed, the motion of the Earth contradicts what the Christian bible states. Galileo was convinced that *truth* was determined by observation, the Inquisition that it was determined by a book – and by itself. In many letters that Galileo wrote throughout his life he expressed his conviction that observational truth could never be a heresy. The trial showed him the opposite: he was forced to state that he erred in teaching that the Earth Ref. 199 moves. After a while, the Pope reduced the prison sentence to house arrest.

Galileo's condemnation on the motion of the Earth was not the end of the story. In the years after Galileo's death, also atomism was condemned in several trials against Galileo's ideas and his followers. But the effects of these trials were not those planned by the Inquisition. Only twenty years after the famous trial, around 1650, every astronomer in the world was convinced of the motion of the Earth. And the result of the trials against atomism was that at the end of the 17th century, practically every scientist in the world was convinced that atoms exist. The trials accelerated an additional effect: after Galileo and Descartes, the centre of scientific research and innovation shifted from Catholic countries, like Italy or France, to protestant countries. In these, such as the Netherlands, England, Germany or the Scandinavian countries, the Inquisition had no power. This shift is still felt today.

It is a sad story that in 1992, the Catholic church did not revoke Galileo's condemnation. In that year, Pope John Paul II gave a speech on the Galileo case. Many years before, he had asked a study commission to re-evaluate the trial, because he wanted to express his regrets for what had happened and wanted to rehabilitate Galileo. The commission Ref. 201 worked for twelve years. But the bishop that presented the final report was a crook: he avoided citing the results of the study commission, falsely stated the position of both parties on the subject of truth, falsely stated that Galileo's arguments on the motion of the Earth were weaker than those of the church, falsely summarized the past positions of the church on the motion of the Earth, avoided stating that prison sentences are not good arguments in issues of opinion or of heresy, made sure that rehabilitation was not even discussed, and of course, avoided any mention of transubstantiation. At the end of this power struggle, Galileo was thus *not* rehabilitated, in contrast to what the Pope wanted and in contrast to what most press releases of the time said; the Pope only stated that 'errors were made on both sides', and the crook behind all this was rewarded with a promotion.*

But that is not the end of the story. The documents of the trial, which were kept locked when Redondi made his discovery, were later made accessible to scholars by Pope John Paul II. In 1999, this led to the discovery of a new document, called EE 291, an internal expert opinion the atom issue that was written for the trial in 1632, a few months before the Ref. 200 start of the procedure. The author of the document comes to the conclusion that Galileo was indeed a heretic in the matter of atoms. The document thus proves that the cover-up

* We should not be too indignant: the same situation happens in many commercial companies every day; most industrial employees can tell similar stories.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of the transubstantiation issue during the trial of Galileo must have been systematic and thorough, as Redondi had deduced. Indeed, church officials and the Catholic catechism carefully avoid the subject of atoms even today; you can search the Vatican website www.vatican.va for any mention of them.

But Galileo did not want to attack transubstantiation; he wanted to advance the idea of atoms. And he did. Despite being condemned to prison in his trial, Galileo published his last book, the *Discorsi*, written as a blind old man under house arrest, on atoms. It is an irony of history that today, quantum theory, named by Max Born after the term used by Galileo for atoms, has become the most precise description of nature yet.

Page 976

How high can animals jump?

Fleas can jump to heights a hundred times their size, humans only to heights about their own size. In fact, biological studies yield a simple observation: most animals, regardless of their size, achieve about the same jumping height, namely between 0.8 and 2.2 m, whether they are humans, cats, grasshoppers, apes, horses or leopards. We have explained this fact earlier on.

Ref. 202

Page 77

At first sight, the observation of constant jumping height seems to be a simple example of scale invariance. But let us look more closely. There are some interesting exceptions at both ends of the mass range. At the small end, mites and other small insects do not achieve such heights because, like all small objects, they encounter the problem of air resistance. At the large end, elephants do not jump that high, because doing so would break their bones. But why do bones break at all?

Why are all humans of about the same size? Why are there no giant adults with a height of ten metres? Why aren't there any land animals larger than elephants? The answer, already given by Galileo, yields the key to understanding the structure of matter. The materials of which people and animals are made would not allow such changes of scale, as the bones of giants would collapse under the weight they have to sustain. Bones have a finite strength because their constituents stick to each other with a finite attraction. Continuous matter – which exists only in cartoons – could not break at all, and fractal matter would be infinitely fragile. Matter breaks under finite loads because it is composed of small basic constituents.

Felling trees

The gentle lower slopes of Motion Mountain are covered by trees. Trees are fascinating structures. Take their size. Why do trees have limited size? Already in the sixteenth century, Galileo knew that it is not possible to increase tree height without limits: at some point a tree would not have the strength to support its own weight. He estimated the maximum height to be around 90 m; the actual record, unknown to him at the time, seems to be 150 m, for the Australian tree *Eucalyptus regnans*. But why does a limit exist at all? The answer is the same as for bones: wood has a finite strength because it is not scale invariant; and it is not scale invariant because it is made of small constituents, namely atoms.*

Ref. 203

* There is another important limiting factor: the water columns inside trees must not break. Both factors seem to yield similar limiting heights.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

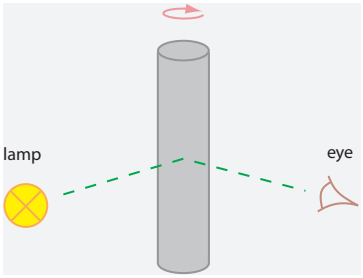

FIGURE 163 Atoms exist: rotating an illuminated, perfectly round single crystal aluminium rod leads to brightness oscillations because of the atoms that make it up

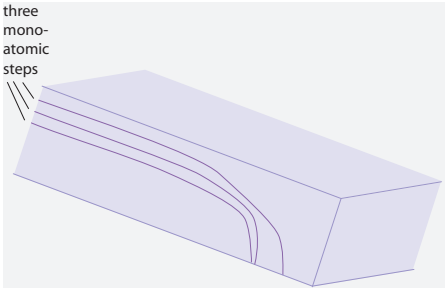

FIGURE 164 Atomic steps in broken gallium arsenide crystals (wafers) can be seen under a light microscope

In fact, the derivation of the precise value of the height limit is more involved. Trees must not break under strong winds. Wind resistance limits the height-to-thickness ratio h/d to about 50 for normal-sized trees (for $0.2\,\mathrm{m} < d < 2\,\mathrm{m}$). Can you say why? Thinner trees are limited in height to less than 10 m by the requirement that they return to the vertical after being bent by the wind.

Challenge 468 ny

Ref. 204

Such studies of natural constraints also answer the question of why trees are made from wood and not, for example, from steel. You could check for yourself that the maximum height of a column of a given mass is determined by the ratio E/ρ^2 between the elastic module and the square of the mass density. For a long time, wood was actually the material for which this ratio was highest. Only recently have material scientists managed to engineer slightly better ratios with fibre composites.

Challenge 469 s

Ref. 205

Why do materials break at all? All observations yield the same answer and confirm Galileo's reasoning: because there is a smallest size in materials. For example, bodies under stress are torn apart at the position at which their strength is minimal. If a body were completely homogeneous, it could not be torn apart; a crack could not start anywhere. If a body had a fractal Swiss-cheese structure, cracks would have places to start, but they would need only an infinitesimal shock to do so.

A simple experiment that shows that solids have a smallest size is shown in Figure 163. A cylindrical rod of pure, single crystal aluminium shows a surprising behaviour when it is illuminated from the side: its brightness depends on how the rod is oriented, even though it is completely round. This angular dependence is due to the atomic arrangement of the aluminium atoms in the rod.

It is not difficult to confirm experimentally the existence of smallest size in solids. It is sufficient to break a single crystal, such as a gallium arsenide wafer, in two. The breaking surface is either completely flat or shows extremely small steps, as shown in Figure 164. These steps are visible under a normal light microscope. (Why?) It turns out that all the step heights are multiples of a smallest height: its value is about 0.2 nm. The existence of a smallest height, corresponding to the height of an atom, contradicts all possibilities of scale invariance in matter.

Challenge 470 ny

The sound of silence

Climbing the slopes of Motion Mountain, we arrive in a region of the forest covered with deep snow. We stop for a minute and look around. It is dark; all the animals are asleep; there is no wind and there are no sources of sound. We stand still, without breathing, and listen to the silence. (You can have this experience also in a sound studio such as those used for musical recordings, or in a quiet bedroom at night.) In situations of complete silence, the ear automatically becomes more sensitive*; we then have a strange experience. We hear two noises, a lower- and a higher-pitched one, which are obviously generated inside the ear. Experiments show that the higher note is due to the activity of the nerve cells in the inner ear. The lower note is due to pulsating blood streaming through the head. But why do we hear a noise at all?

Many similar experiments confirm that whatever we do, we can never eliminate noise from measurements. This unavoidable type of noise is called *shot noise* in physics. The statistical properties of this type of noise actually correspond precisely to what would be expected if flows, instead of being motions of continuous matter, were transportation of a large number of equal, small and discrete entities. Thus, simply listening to noise proves that electric current is made of electrons, that air and liquids are made of molecules, and that light is made of photons. In a sense, the sound of silence is the sound of atoms. Shot noise would not exist in continuous systems.

Little hard balls

> “I prefer knowing the cause of a single thing to being king of Persia.”
>
> Democritus

Precise observations show that matter is neither continuous nor a fractal: matter is made of smallest basic particles. Galileo, who deduced their existence by thinking about giants and trees, called them ‘smallest quanta.’ Today they are called ‘atoms’, in honour of

Planck pressure (maximum pressure possible in nature)	$4.6 \cdot 10^{113}$ Pa

a famous argument of the ancient Greeks. Indeed, 2500 years ago, the Greeks asked the following question. If motion and matter are conserved, how can change and transformation exist? The philosophical school of Leucippus and Democritus of Abdera* studied

* Leucippus of Elea (Λευκιππος) (*c.* 490 to *c.* 430 BCE), Greek philosopher; Elea was a small town south of Naples. It lies in Italy, but used to belong to the Magna Graecia. Democritus (Δεμοκριτος) of Abdera (*c.* 460 to *c.* 356 or 370 BCE), also a Greek philosopher, was arguably the greatest philosopher who ever lived. Together with his teacher Leucippus, he was the founder of the atomic theory; Democritus was a much admired thinker, and a contemporary of Socrates. The vain Plato never even mentions him, as Democritus was a danger to his own fame. Democritus wrote many books which all have been lost; they were not copied during the Middle Ages because of his scientific and rational world view, which was felt to be a danger by religious zealots who had the monopoly on the copying industry. Nowadays, it has become common to

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

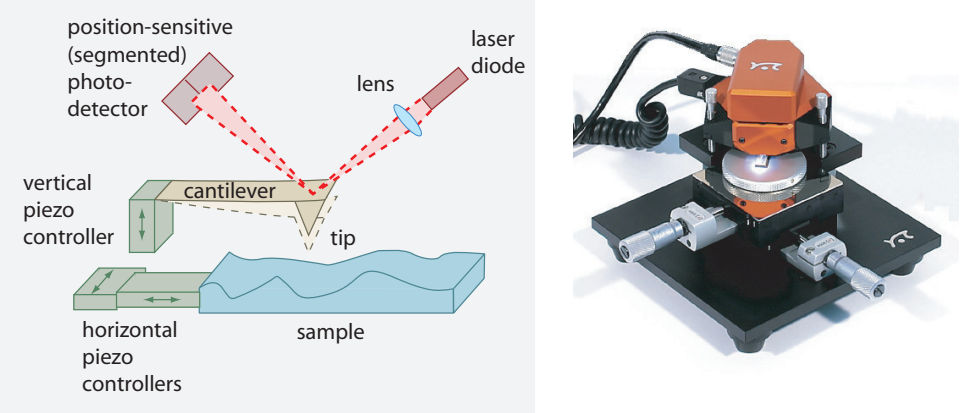

FIGURE 166 The principle and a realization of an atomic force microscope (photograph © Nanosurf)

two particular observations in special detail. They noted that salt dissolves in water. They also noted that fish can swim in water. In the first case, the volume of water does not increase when the salt is dissolved. In the second case, when fish advance, they must push water aside. Leucippus and Democritus deduced that there is only one possible explanation that satisfies observations and also reconciles conservation and transformation: nature is made of void and of small, indivisible and conserved particles.* In this way any example of motion, change or transformation is due to rearrangements of these particles; change and conservation are thus reconciled.

In short, since matter is hard, has a shape and is divisible, Leucippus and Democritus imagined it as being made of atoms. Atoms are particles which are hard, have a shape, but are indivisible. In other words, the Greeks imagined nature as a big Lego set. Lego pieces are first of all hard or *impenetrable*, i.e., repulsive at very small distances. They are *attractive* at small distances: they remain stuck together. Finally, they have *no interaction* at large distances. Atoms behave in the same way. (Actually, what the Greeks called 'atoms' partly corresponds to what today we call 'molecules'. The latter term was invented by Amadeo Avogadro in 1811 in order to clarify the distinction. But we can forget this detail for the moment.)

Since atoms are invisible, it took many years before all scientists were convinced by the experiments showing their existence. In the nineteenth century, the idea of atoms was Page 286 beautifully verified by the discovery of the 'laws' of chemistry and those of gas behaviour.

claim – incorrectly – that Democritus had no proof for the existence of atoms. That is a typical example of disinformation with the aim of making us feel superior to the ancients.

* The story is told by Lucretius, in full Titus Lucretius Carus, in his famous text *De rerum natura*, around 60 BCE. (An English translation can be found on perseus.uchicago.edu/hopper/text.jsp?doc=Perseus:text:1999.02.0131.) Lucretius relates many other proofs; in Book 1, he shows that there is vacuum in solids – as proven by porosity and by density differences – and in gases – as proven by wind. He shows that smells are Challenge 471 ny due to particles, and that so is evaporation. (Can you find more proofs?) He also explains that the particles cannot be seen due to their small size, but that their effects can be felt and that they allow to consistently explain all observations.

Especially if we the imagine particles as little balls, we cannot avoid calling this a typically male idea. Challenge 472 d (What would be the female approach?)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

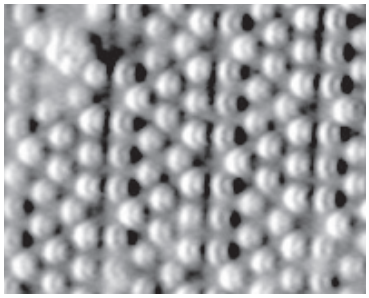

FIGURE 167 The atoms on the surface of a silicon crystal, mapped with an atomic force microscope (© Universität Augsburg)

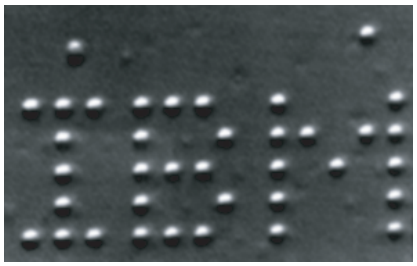

FIGURE 168 The result of moving helium atoms on a metallic surface (© IBM)

Later on, the noise effects were discovered.

Nowadays, with advances in technology, single atoms can be seen, photographed, Ref. 208, Ref. 209 hologrammed, counted, touched, moved, lifted, levitated, and thrown around. And indeed, like everyday matter, atoms have mass, size, shape and colour. Single atoms have Ref. 210 even been used as lamps and lasers.

Modern researchers in several fields have fun playing with atoms in the same way that children play with Lego. Maybe the most beautiful demonstration of these possibilities Ref. 211 is provided by the many applications of the atomic force microscope. If you ever have the opportunity to use one, do not miss it! An atomic force microscope is a simple tabletop device which follows the surface of an object with an atomically sharp needle;* such Ref. 212 needles, usually of tungsten, are easily manufactured with a simple etching method. The changes in the height of the needle along its path over the surface are recorded with the help of a deflected light ray. With a little care, the atoms of the object can be felt and made visible on a computer screen. With special types of such microscopes, the needle can be used to move atoms one by one to specified places on the surface. It is also possible to scan a surface, pick up a given atom and throw it towards a mass spectrometer to determine Ref. 213 what sort of atom it is.

Incidentally, the construction of atomic force microscopes is only a small improvement on what nature is building already by the millions; when we use our ears to listen, we are actually detecting changes in eardrum position of about 1 nm. In other words, we all have two 'atomic force microscopes' built into our heads.

In summary, matter is not scale invariant: in particular, it is neither smooth nor fractal. Matter is made of atoms. Different types of atoms, as well as their various combinations, produce different types of substances. Pictures from atomic force microscopes show that the size and arrangement of atoms produce the *shape* and the *extension* of objects, confirming the Lego model of matter.** As a result, the description of the motion of extended objects can be reduced to the description of the motion of their atoms. Atomic motion

* A cheap version costs only a few thousand euro, and will allow you to study the difference between a silicon wafer – crystalline – a flour wafer – granular-amorphous – and a consecrated wafer.

** Studying matter in even more detail yields the now well-known idea that matter, at higher and higher magnifications, is made of molecules, atoms, nuclei, protons and neutrons, and finally, quarks. Atoms also

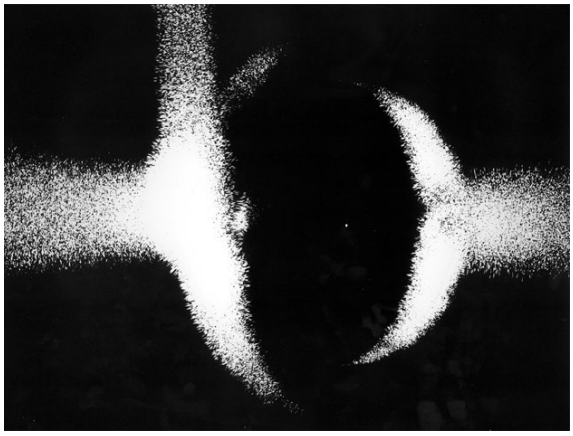

FIGURE 169 A single barium ion levitated in a Paul trap (image size around 2 mm) at the centre of the picture, visible also to the naked eye in the original experiment, performed in 1985 (© Werner Neuhauser)

will be a major theme in the following pages. One of its consequences is especially important: heat. Before we study it, we have a look at fluids.

The motion of fluids

Fluids can be liquids or gases. Their motion can be exceedingly complex, as Figure 170 shows. Such complex motions are often examples of self-organization or chaos; an introduction into such effects is given below.

Ref. 214
Page 302

Like all motion, fluid motion obeys energy conservation. In the case that no energy is transformed into heat, the conservation of energy is particularly simple. Motion that does not generate heat implies the lack of vortices; such fluid motion is called *laminar*. If the speed of the fluid does not depend on time at all positions, it is called *stationary*. For motion that is both laminar and stationary, energy conservation can be expressed with speed v and pressure p:

$$\frac{1}{2}\rho v^2 + p + \rho g h = \text{const} \tag{93}$$

where h is the height above ground. This is called *Bernoulli's equation*.* In this equation,

contain electrons. A final type of matter, neutrinos, is observed coming from the Sun and from certain types of radioactive materials. Even though the fundamental bricks have become smaller with time, the basic idea remains: matter is made of smallest entities, nowadays called elementary particles. In the part of our mountain ascent on quantum theory we will explore this idea in detail. Page 1290 lists the measured properties of all known elementary particles.

Page 1248

* Daniel Bernoulli (b. 1700 Bâle, d. 1782 Bâle), important Swiss mathematician and physicist. His father Johann and his uncle Jakob were famous mathematicians, as were his brothers and some of his nephews. Daniel Bernoulli published many mathematical and physical results. In physics, he studied the separation of compound motion into translation and rotation. In 1738 he published the *Hydrodynamique*, in which he deduced all results from a single principle, namely the conservation of energy. The so-called *Bernoulli equation* states that (and how) the pressure of a fluid decreases when its speed increases. He studied the tides and many complex mechanical problems, and explained the Boyle–Mariotte gas 'law'. For his publications he won the prestigious prize of the French Academy of Sciences – a forerunner of the Nobel Prize – ten times.

FIGURE 171 Daniel Bernoulli (1700–1782)

the first term is the kinetic energy (per volume) of the fluid, and the other two terms are potential energies (per volume). Indeed, the second term is the potential energy (per volume) resulting from the compression of the fluid. Indeed, pressure is a potential energy per volume. The last term is only important if the fluid rises against ground.

Challenge 473 e

Energy conservation implies that the lower the pressure is, the larger the speed of a fluid becomes. One can use this relation to measure the speed of a stationary water flow in a tube. One just has to narrow the tube somewhat at one location along the tube, and measure the pressure difference before and at the tube restriction. One finds that the speed v far from the constriction is given as $v = k\sqrt{p_1 - p_2}$. (What is the constant k?) A device using this method is called a Venturi gauge.

Challenge 474 s

If the geometry of a system is kept fixed and the fluid speed is increased, at a certain speed one observes a transition: the liquid loses its clarity, the flow is not stationary any more. This is seen whenever a water tap is opened. The flow has changed from laminar to turbulent. At this point, Bernoulli's equation is not valid any more.

The description of turbulence might be the toughest of all problems in physics. When the young Werner Heisenberg was asked to continue research on turbulence, he refused – rightly so – saying it was too difficult; he turned to something easier and discovered and developed quantum mechanics instead. Turbulence is such a vast topic, with many of its concepts still not settled, that despite the number and importance of its applications, only now, at the beginning of the twenty-first century, are its secrets beginning to be unravelled. It is thought that the equations of motion describing fluids, the so-called *Navier–Stokes equations*, are sufficient to understand turbulence.* But the mathematics behind them is mind-boggling. There is even a prize of one million dollars offered by the Clay Mathematics Institute for the completion of certain steps on the way to solving the equations.

Ref. 215

Important systems which show laminar flow, vortices and turbulence at the same time are wings and sails. (See Figure 172.) All wings work best in laminar mode. The essence of a wing is that it imparts air a downward velocity with as little turbulence as possible. (The aim to minimize turbulence is the reason that wings are curved. If the engine is very powerful, a flat wing at an angle also works. Strong turbulence is also of advantage for landing safely.) The downward velocity of the trailing air leads to a centrifugal force

* They are named after Claude Navier (b. 1785 Dijon, d. 1836 Paris), important French engineer and bridge builder, and Georges Gabriel Stokes (b. 1819 Skreen, d. 1903 Cambridge), important Irish physicist and mathematician.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 172 The *moth* sailing class: a 30 kg boat that sails above the water using *hydrofoils*, i.e., underwater wings (© Bladerider International)

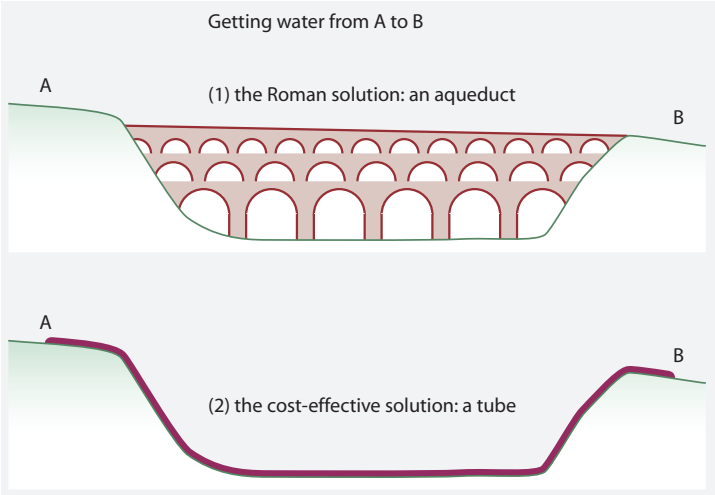

FIGURE 173 Wasting money because of lack of knowledge about fluids

Ref. 216 acting on the air that passes above the wing. This leads to a lower pressure, and thus to lift. (Wings thus do *not* rely on the Bernoulli equation, where lower pressure *along* the flow leads to higher air speed, as unfortunately, many books used to say. Above a wing, the higher speed is related to lower pressure *across* the flow.)

The different speeds of the air above and below the wing lead to vortices at the end of every wing. These vortices are especially important for the take-off of any insect, bird Page 1303 and aeroplane. More details on wings are discussed later on.

Curiosities and fun challenges about fluids

What happens if people do not know the rules of nature? The answer is the same since 2000 years: taxpayer's money is wasted or health is in danger. One of the oldest examples, the aqueducts from Roman time, is shown in Figure 173. They only exist because Romans

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

did not know how fluids move. Now you know why there are no aqueducts any more. But
Challenge 475 s using a 1 or 2 m water hose in this way to transport gasoline can be dangerous. Why?

* *

You bathtub is full of water. You have an unmarked 3-litre container and an unmarked
Challenge 476 e 5-litre container. How can you get 4 litres of water from the bathtub?

* *

What is the speed record for motion under water? Probably nobody knows: it is a military secret. In fact, the answer needs to be split. The fastest published speed for a projectile under water, almost fully enclosed in a gas bubble, is 1550 m/s, faster than the speed of sound in water, achieved over a distance of a few metres in a military laboratory in the 1990s. The fastest system with an engine seems to be a torpedo, also moving mainly in a gas bubble, that reaches over 120 m/s, thus faster than any formula 1 racing car. The exact speed achieved is higher and secret. (The method of enclosing objects under water in gas bubbles, called *supercavitation*, is a research topic of military engineers all over the world.) The fastest fish, the sailfish *Istiophorus platypterus*, reaches 22 m/s, but speeds up to 30 m are suspected. The fastest manned objects are military submarines, whose speeds are secret, but believed to be around 21 m/s. (All military naval engineers in this world, with the enormous budgets they have, are not able to make submarines that are faster than fish. The reason that aeroplanes are faster than birds is evident: aeroplanes were not developed by military engineers.) The fastest human-powered submarines reach around 4 m/s. One can guess that if human-powered submarine developers had the same development budget as military engineers, their machines would probably be faster than nuclear submarines.

There are no record lists for swimming under water. Underwater swimming is known to be faster than above-water breast stroke, back stroke or dolphin stroke: that is the reason that swimming underwater over long distances is forbidden in competitions in these styles. However, it is not known whether crawl-style records are faster or slower than records for the fastest swimming style below water. Which one is faster in your own
Challenge 477 e case?

* *

How much water is necessary to moisten the air in a room in winter? At 0 °C, the vapour pressure of water is 6 mbar, 20 °C it is 23 mbar. As a result, heating air in the winter gives
Challenge 478 e at most a humidity of 25%. To increase the humidity by 50%, one thus needs about 1 litre of water per 100 m^3.

* *

Fluid motion is of vital importance. There are at least four fluid circulation systems inside the human body. First, *air* is circulated inside the lungs by the diaphragm and other chest muscles. Second, *blood* flows through the blood system by the heart. Third, *lymph* flows through the lymphatic vessels, moved passively by body muscles. Fourth, the *cerebrospinal fluid* circulates aorund the brain and the spine, moved by motions of the head. For this reason, medical doctors like the simple statement: every illness is ultimately due to bad circulation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 479 e Why do animals have blood and other circulation systems? Because fluid diffusion is too slow. Can you detail the argument?

* *

Challenge 480 ny All animals have similar blood circulation speeds, namely between 0.2 m/s and 0.4 m/s. Why?

* *

Challenge 481 s Liquid pressure depends on height. If the average human blood pressure at the height of the heart is 13.3 kPa, can you guess what it is inside the feet when standing?

* *

Challenge 482 s The human heart pumps blood at a rate of about 0.1 l/s. A tyical capillary has the diameter of a red blood cell, around 7 µm, and in it the blood moves at a speed of half a millimetre per second. How many capillaries are there in a human?

* *

Challenge 483 s You are in a boat on a pond with a stone, a bucket of water and a piece of wood. What happens to the water level of the pond after you throw the stone in it? After you throw the water into the pond? After you throw the piece of wood?

* *

Challenge 484 s A ship leaves a river and enter the sea. What happens?

* *

Challenge 485 e Put a rubber air balloon over the end of a bottle and let it hang inside the bottle. How much can you blow up the balloon inside the bottle?

* *

Challenge 486 e Put a small paper ball into the neck of a horizontal bottle and try to blow it into the bottle. The paper will fly *towards* you. Why?

* *

Challenge 487 e It is possible to blow an egg from one egg-cup to a second one just behind it. Can you perform this trick?

* *

Challenge 488 s In the seventeenth century, engineers who needed to pump water faced a challenge. To pump water from mine shafts to the surface, no water pump managed more than 10 m of height difference. For twice that height, one always needed two pumps in series, connected by an intermediate reservoir. Why? How then do trees manage to pump water upwards for larger heights?

* *

When hydrogen and oxygen are combined to form water, the amount of hydrogen needed is exactly twice the amount of oxygen, if no gas is to be left over after the reaction.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

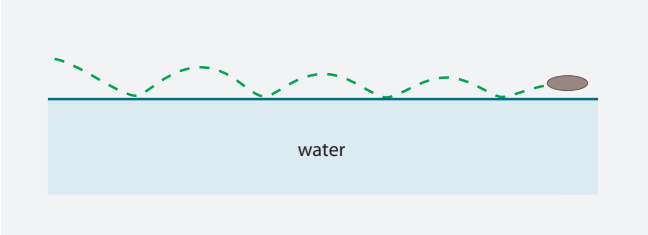

FIGURE 174 What is your personal stone-skipping record?

Challenge 489 s How does this observation confirm the existence of atoms?

* *

Challenge 490 s How are alcohol-filled chocolate pralines made? Note that the alcohol is not injected into them afterwards, because there would be no way to keep the result tight enough.

* *

How often can a stone jump when it is thrown over the surface of water? The present world record was achieved in 2002: 40 jumps. More information is known about the previous world record, achieved in 1992: a palm-sized, triangular and flat stone was thrown with a speed of 12 m/s (others say 20 m/s) and a rotation speed of about 14 revolutions per second along a river, covering about 100 m with 38 jumps. (The sequence was filmed with a video recorder from a bridge.)

Ref. 217

What would be necessary to increase the number of jumps? Can you build a machine that is a better thrower than yourself?

Challenge 491 r

* *

The most important component of air is nitrogen (about 78 %). The second component is oxygen (about 21 %). What is the third one?

Challenge 492 s

* *

Which everyday system has a pressure lower than that of the atmosphere and usually kills a person if the pressure is raised to the usual atmospheric value?

Challenge 493 s

* *

Water can flow uphill: Heron's fountain shows this most clearly. Heron of Alexandria (*c.* 10 to *c.* 70) described it 2000 years ago; it is easily built at home, using some plastic bottles and a little tubing. How does it work?

Challenge 494 s

* *

A light bulb is placed, underwater, in a stable steel cylinder with a diameter of 16 cm. A Fiat Cinquecento car (500 kg) is placed on a piston pushing onto the water surface. Will the bulb resist?

Challenge 495 s

* *

Challenge 496 s What is the most dense gas? The most dense vapour?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

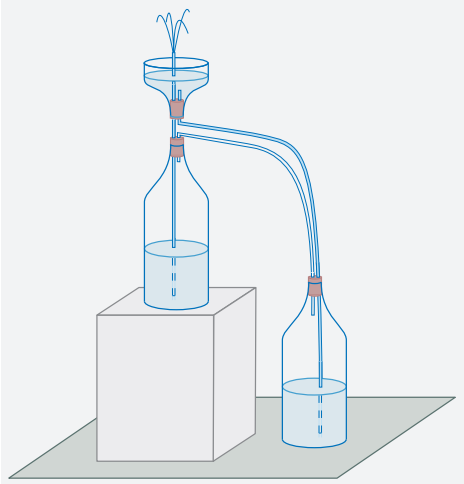

FIGURE 175 Heron's fountain

* *

Every year, the Institute of Maritime Systems of the University of Rostock organizes a contest. The challenge is to build a paper boat with the highest carrying capacity. The paper boat must weigh at most 10 g and fulfil a few additional conditions; the carrying capacity is measured by pouring lead small shot onto it, until the boat sinks. The 2008 record stands at 5.1 kg. Can you achieve this value? (For more information, see the www.paperboat.de website.)

Challenge 497 e

* *

A modern version of an old question – already posed by Daniel Colladon (1802–1893) – is the following. A ship of mass m in a river is pulled by horses walking along the river bank attached by ropes. If the river is of superfluid helium, meaning that there is no friction between ship and river, what energy is necessary to pull the ship upstream along the river until a height h has been gained?

Challenge 498 s

* *

An urban legend pretends that at the bottom of large waterfalls there is not enough air to breathe. Why is this wroong?

Challenge 499 e

* *

The Swiss physicist and inventor Auguste Piccard (1884–1962) was a famous explorer. Among others, he explored the stratosphere: he reached the record height of 16 km in his *aerostat*, a hydrogen gas balloon. Inside the airtight cabin hanging under his balloon, he had normal air pressure. However, he needed to introduce several ropes attached at the balloon into the cabin, in order to be able to pull and release them, as they controlled his balloon. How did he get the ropes into the cabin while at the same time preventing air from leaving?

Challenge 500 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

A human cannot breathe at any depth under water, even if he has a tube going to the surface. At a few metres of depth, trying to do so is inevitably fatal! Even at a depth of
Challenge 501 s 60 cm only, the human body can only breathe in this way for a few minutes. Why?

* *

A human in air falls with a limiting speed of about 50 m/s (the precise value depends on clothing). How long does it take to fall from a plane at 3000 m down to a height of
Challenge 502 ny 200 m?

* *

To get an idea of the size of Avogadro's and Loschmidt's number, two questions are usually asked. First, on average, how many molecules or atoms that you breathe in with every breath have previously been exhaled by Caesar? Second, on average, how many atoms of
Challenge 503 s Jesus do you eat every day? Even though the Earth is large, the resulting numbers are still telling.

* *

A few drops of tea usually flow along the underside of the spout of a teapot (or fall onto the table). This phenomenon has even been simulated using supercomputer simula-
Ref. 218 tions of the motion of liquids, by Kistler and Scriven, using the Navier–Stokes equations. Teapots are still shedding drops, though.

* *

The best giant soap bubbles can be made by mixing 1.5 l of water, 200 ml of corn syrup and 450 ml of washing-up liquid. Mix everything together and then let it rest for four hours. You can then make the largest bubbles by dipping a metal ring of up to 100 mm
Challenge 504 s diameter into the mixture. But why do soap bubbles burst?

* *

A drop of water that falls into a pan containing hot oil dances on the surface for a considerable time, if the oil is above 220 °C. Cooks test the temperature of oil in this way.
Challenge 505 ny Why does this so-called *Leidenfrost effect** take place? The Leidenfrost effect allows one to plunge the bare hand into molten lead, to keep liquid nitrogen in one's mouth, to check whether a pressing iron is hot, or to walk over hot coal – if one follows several safety rules,
Ref. 219 as explained by Jearl Walker. (Do *not* try this yourself! Many things can go wrong.) The main condition is that the hand, the mouth or the feet must be wet. Walker lost two teeth in a demonstration and badly burned his feet in a walk when the condition was not met.

* *

Challenge 506 s Why don't air molecules fall towards the bottom of the container and stay there?

* *

Challenge 507 s Which of the two water funnels in Figure 176 is emptied more rapidly? Apply energy

* It is named after Johann Gottlieb Leidenfrost (1715–1794), German physician.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

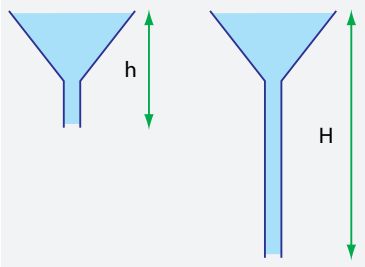

FIGURE 176 Which funnel is faster?

Ref. 220 conservation to the fluid's motion (the Bernoulli equation) to find the answer.

* *

As we have seen, fast flow generates an underpressure. How do fish prevent their eyes
Challenge 508 s from popping when they swim rapidly?

* *

Golf balls have dimples for the same reasons that tennis balls are hairy and that shark and dolphin skin is not flat: deviations from flatness reduce the flow resistance because
Challenge 509 ny many small eddies produce less friction than a few large ones. Why?

* *

The recognized record height reached by a helicopter is 12 442 m above sea level, though 12 954 m has also been claimed. (The first height was reached in 1972, the second in 2002, both by French pilots in French helicopters.) Why, then, do people still continue to use their legs in order to reach the top of Mount Sagarmatha, the highest mountain in the
Challenge 510 s world?

* *

A loosely knotted sewing thread lies on the surface of a bowl filled with water. Putting a bit of washing-up liquid into the area surrounded by the thread makes it immediately
Challenge 511 e become circular. Why?

* *

Challenge 512 s How can you put a handkerchief under water using a glass, while keeping it dry?

* *

Are you able to blow a ping-pong ball out of a funnel? What happens if you blow through a funnel towards a burning candle?

* *

The fall of a leaf, with its complex path, is still a topic of investigation. We are far from being able to predict the time a leaf will take to reach the ground; the motion of the air around a leaf is not easy to describe. One of the simplest phenomena of hydrodynamics remains one of its most difficult problems.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 177 A smoke ring, around 100 m in size, ejected from Etna's Bocca Nova in 2000 (© Daniela Szczepanski at www.vulkanarchiv.de and www.vulkane.net)

* *

Fluids exhibit many interesting effects. Soap bubbles in air are made of a thin spherical film of liquid with air on both sides. In 1932, anti-bubbles, thin spherical films of air with liquid on both sides, were first observed. In 2004, the Belgian physicist Stéphane Dorbolo and his team showed that it is possible to produce them in simple experiments, and in particular, in Belgian beer.

Ref. 221

Have you ever dropped a Mentos candy into a Diet Coca Cola bottle? You will get an interesting effect. (Do it at your own risk...) Is it possible to build a rocket in this way?

Challenge 513 e

* *

A needle can swim on water, if you put it there carefully. Just try, using a fork. Why does it float?

Challenge 514 e

* *

The Rhine emits about 2 300 m^3/s of water into the North Sea, the Amazon River about 120 000 m^3/s into the Atlantic. How much is this less than $c^3/4G$?

Challenge 515 e

* *

Fluids exhibit many complex motions. To see an overview, have a look at the beautiful collection on the web site serve.me.nus.edu.sg/limtt. Among fluid motion, vortex rings, as emitted by smokers or volcanoes, have often triggered the imagination. (See Figure 177.) One of the most famous examples of fluid motion is the leapfrogging of vortex rings, shown in Figure 178. Lim Tee Tai explains that more than two leapfrogs are extremely hard to achieve, because the slightest vortex ring misalignment leads to the collapse of

Challenge 516 e

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

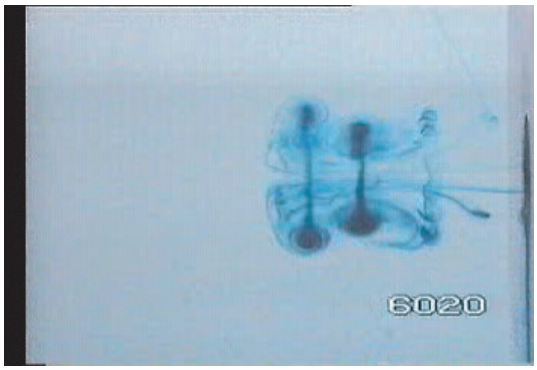

FIGURE 178 Two leapfrogging vortex rings (QuickTime film © Lim Tee Tai)

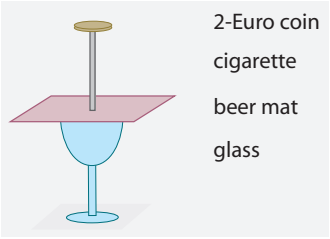

FIGURE 179 How can you move the coin into the glass without touching anything?

Ref. 222 the system.

Curiosities and fun challenges about solids

Glass is a solid. Nevertheless, many textbooks say that glass is a liquid. This error has been propagated for about a hundred years, probably originating from a mistranslation of a sentence in a German textbook published in 1933 by Gustav Tamman, *Der Glaszustand*.

Challenge 517 s Can you give at least three reasons why glass is a solid and not a liquid?

* *

What is the maximum length of a vertically hanging wire? Could a wire be lowered from

Challenge 518 s a suspended geostationary satellite down to the Earth? This would mean we could realize a space 'lift'. How long would the cable have to be? How heavy would it be? How would you build such a system? What dangers would it face?

* *

Physics is often good to win bets. See Figure 179 for a way to do so, due to Wolfgang Stalla.

* *

Matter is made of atoms. Over the centuries the stubborn resistance of many people

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

to this idea has lead to the loss of many treasures. For over a thousand years, people thought that genuine pearls could be distinguished from false ones by hitting them with a hammer: only false pearls would break. However, *all* pearls break. (Also diamonds break in this situation.) Due to this belief, over the past centuries, all the most beautiful pearls in the world have been smashed to pieces.

* *

Comic books have difficulties with the concept of atoms. Could Asterix really throw Romans into the air using his fist? Are Lucky Luke's precise revolver shots possible? Can Spiderman's silk support him in his swings from building to building? Can the Roadrunner stop running in three steps? Can the Sun be made to stop in the sky by command? Can space-ships hover using fuel? Take any comic-book hero and ask yourself whether
Challenge 519 e matter made of atoms would allow him the feats he seems capable of. You will find that most cartoons are comic precisely because they assume that matter is not made of atoms, but continuous! In a sense, atoms make life a serious adventure.

* *

Can humans start earthquakes? What would happen if 1000 million Indians were to jump
Challenge 520 s at the same time from the kitchen table to the floor?

In fact, several strong earthquakes *have* been triggered by humans. This has happened when water dams have been filled, or when water has been injected into drilling holes. It has also been suggested that the extraction of deep underground water also causes earthquakes. If this is confirmed by future research, a sizeable proportion of all earthquakes could be human-triggered.

* *

Challenge 521 s How can a tip of a stalactite be distinguished from a tip of a stalagmite? Does the difference exist also for icicles?

* *

How much more weight would your bathroom scales show if you stood on them in a
Challenge 522 s vacuum?

* *

One of the most complex extended bodies is the human body. In modern simulations of the behaviour of humans in car accidents, the most advanced models include ribs, vertebrae, all other bones and the various organs. For each part, its specific deformation properties are taken into account. With such models and simulations, the protection of passengers and drivers in cars can be optimized.

* *

The deepest hole ever drilled into the Earth is 12 km deep. In 2003, somebody proposed to enlarge such a hole and then to pour millions of tons of liquid iron into it. He claimed that the iron would sink towards the centre of the Earth. If a measurement device communication were dropped into the iron, it could send its observations to the surface using
Challenge 523 s sound waves. Can you give some reasons why this would not work?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 39 Steel types, properties and uses

Ferritic steel	Austenitic steel	Martensitic steel
Definition		
'usual' steel	'soft' steel	hardened steel, brittle
body centred cubic (bcc)	face centred cubic (fcc)	body centred tetragonal (bct)
iron and carbon	iron, chromium, nickel, manganese, carbon	carbon steel and alloys
Examples		
construction steel	most stainless (18/8 Cr/Ni) steels	knife edges
car sheet steel	kitchenware	drill surfaces
ship steel	food industry	spring steel, crankshafts
12 % Cr stainless ferrite	Cr/V steels for nuclear reactors	
Properties		
phases described by the iron-carbon phase diagram	phases described by the Schaeffler diagram	phases described by the iron-carbon diagram and the TTT (time–temperature transformation) diagram
in equilibrium at RT	some alloys in equilibrium at RT	not in equilibrium at RT, but stable
mechanical properties and grain size depend on heat treatment	mechanical properties and grain size depend on thermo-mechanical pre-treatment	mechanical properties and grain size strongly depend on heat treatment
hardened by reducing grain size, by forging, by increasing carbon content or by nitration	hardened by cold working only	hard anyway – made by laser irradiation, induction heating, etc.
grains of ferrite and paerlite, with cementite (Fe_3C)	grains of austenite	grains of martensite
ferromagnetic	not magnetic or weakly magnetic	ferromagnetic

* *

The economic power of a nation has long been associated with its capacity to produce high-quality steel. Indeed, the Industrial Revolution started with the mass production of steel. Every scientist should know the basics facts about steel. *Steel* is a combination of iron and carbon to which other elements, mostly metals, may be added as well. One can distinguish three main types of steel, depending on the crystalline structure. *Ferritic steels* have a body-centred cubic structure, as shown in Figure 180, *austenitic steels* have a face-centred cubic structure, and *martensitic steels* have a body-centred tetragonal structure. Table 39 gives further details.

* *

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 180 Ferritic steels are bcc (body centred cubic), as shown by the famous *Atomium* in Brussels, a section of an iron crystal magnified to a height of over 100 m (photo and building are © Asbl Atomium Vzw – SABAM Belgium 2007)

A simple phenomenon which requires a complex explanation is the cracking of a whip. Since the experimental work of Peter Krehl it has been known that the whip cracks when the tip reaches a velocity of *twice* the speed of sound. Can you imagine why?

ples of what engineers do are shown in Figure 182.

Summary on extension

In the case of matter, there are no arbitrary small parts. Matter is made of countable components. This result has been confirmed for solids, liquids and gases. The discreteness of matter is one of the most important results of physics. Matter consists of atoms.

It will be shown later on that the discreteness is itself a consequence of the existence of a smallest change in nature.

What can move in nature? – Flows

Before we continue to the next way to describe motion globally, we will have a look at the possibilities of motion in everyday life. One overview is given in Table 40. The domains that belong to everyday life – motion of fluids, of matter, of matter types, of heat, of light and of charge – are the domains of continuum physics.

Within continuum physics, there are three domains we have not yet studied: the motion of charge and light, called electrodynamics, the motion of heat, called thermodynamics, and the motion of the vacuum. Once we have explored these domains, we will have completed the first step of our description of motion: continuum physics. In continuum physics, motion and moving entities are described with continuous quantities that can take any value, including arbitrarily small or arbitrarily large values.

But nature is *not* continuous. We have already seen that matter cannot be indefinitely divided into ever-smaller entities. In fact, we will discover that there are precise experiments that provide limits to the observed values for *every* domain of continuum physics. There is a limit to mass, to speed, to angular momentum, to force, to entropy and to change of charge. The consequences of these discoveries form the second step in our description of motion: quantum theory and relativity. Quantum theory is based on lower limits; relativity is based on upper limits. The third and last step of our description of motion will be formed by the unification of quantum theory and general relativity.

Every domain of physics, regardless of which one of the above steps it belongs to, describes change in terms two quantities: energy, and an extensive quantity characteristic of the domain. An observable quantity is called *extensive* if it increases with system size. Ref. 228 Table 40 provides an overview. The intensive and extensive quantities corresponding to what in everyday language is called 'heat' are *temperature* and *entropy*.

TABLE 40 Extensive quantities in nature, i.e., quantities that *flow* and *accumulate*

Domain	Extensive quantity (energy carrier)	Current (flow intensity)	Intensive quantity (driving strength)	Energy flow (power)	Resistance to transport (intensity of entropy generation)
Rivers	mass m	mass flow m/t	height difference gh	$P = gh\,m/t$	$R_m = ght/m$ $[m^2/s\,kg]$
Gases	volume V	volume flow V/t	pressure p	$P = pV/t$	$R_V = pt/V$ $[kg/s\,m^5]$
Mechanics	momentum $\boldsymbol{p}$	force $\boldsymbol{F} = d\boldsymbol{p}/dt$	velocity $\boldsymbol{v}$	$P = \boldsymbol{v}\,F$	$R_p = t/m$ $[s/kg]$
	angular momentum $\boldsymbol{L}$	torque $\boldsymbol{M} = d\boldsymbol{L}/dt$	angular velocity $\boldsymbol{\omega}$	$P = \boldsymbol{\omega}\,\boldsymbol{M}$	$R_L = t/mr^2$ $[s/kg\,m^2]$
Chemistry	amount of substance n	substance flow $I_n = dn/dt$	chemical potential μ	$P = \mu\,I_n$	$R_n = \mu t/n$ $[Js/mol^2]$
Thermodynamics	entropy S	entropy flow $I_S = dS/dt$	temperature T	$P = T\,I_S$	$R_S = Tt/S$ $[K^2/W]$
Light	like all massless radiation, it can flow but cannot accumulate				
Electricity	charge q	electrical current $I = dq/dt$	electrical potential U	$P = U\,I$	$R = U/I$ $[\Omega]$
Magnetism	no accumulable magnetic sources are found in nature				
Nuclear physics	extensive quantities exist, but do not appear in everyday life				
Gravitation	empty space can move and flow, but the motion is not observed in everyday life				

FIGURE 183 Sometimes unusual moving objects cross German roads (© RWE)

Chapter 12

FROM HEAT TO TIME-INVARIANCE

Spilled milk never returns into its container by itself. Any hot object, left alone, cools down with time; it never heats up. These and many other observations show that numerous processes in nature are *irreversible*. Does this mean that motion is not time-reversal-invariant, as Nobel Prize winner Ilya Prigogine thought? We discuss the issue in this section.

All irreversible phenomena involve heat. Thus we need to know the basic facts about heat in order to discuss irreversibility. The main points that are taught in high school are almost sufficient.

Ref. 229

Temperature

Macroscopic bodies, i.e., bodies made of many atoms, have temperature. The temperature of a macroscopic body is an aspect of its state. It is observed that any two bodies in contact tend towards the *same* temperature: temperature is contagious. In other words, temperature describes an equilibrium situation. The existence and contagiousness of temperature is often called the *zeroth principle of thermodynamics*. Heating is the increase of temperature, cooling its decrease.

How is temperature measured? The eighteenth century produced the clearest answer: temperature is best defined and measured by the *expansion of gases*. For the simplest, so-called *ideal* gases, the product of pressure p and volume V is proportional to temperature:

$$pV \sim T \,. \tag{94}$$

The proportionality constant is fixed by the *amount* of gas used. (More about it shortly.) The ideal gas relation allows us to determine temperature by measuring pressure and volume. This is the way (absolute) temperature has been defined and measured for about a century. To define the *unit* of temperature, one only has to fix the amount of gas used. It is customary to fix the amount of gas at 1 mol; for oxygen this is 32 g. The proportionality constant, called the *ideal gas constant* R, is defined to be $R = 8.3145\,\mathrm{J/mol\,K}$. This number has been chosen in order to yield the best approximation to the independently defined Celsius temperature scale. Fixing the ideal gas constant in this way defines 1 K, or one Kelvin, as the unit of temperature. In simple terms, a temperature increase of one Kelvin is defined as the temperature increase that makes the volume of an ideal gas increase – keeping the pressure fixed – by a fraction of 1/273.15 or 0.3661 %.

Ref. 230
Page 909
Challenge 526 ny

In general, if one needs to determine the temperature of an object, one takes a mole of

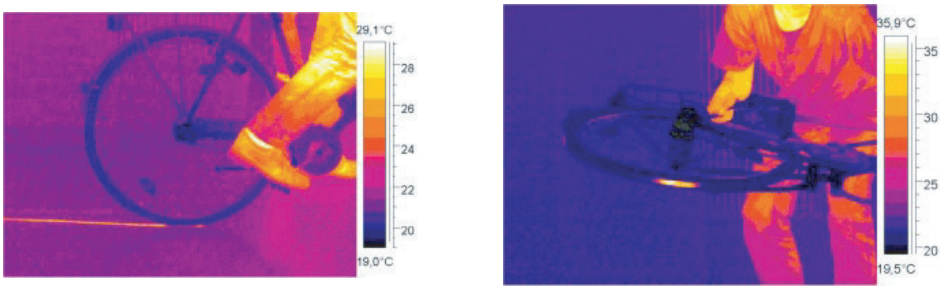

FIGURE 184 Braking generates heat on the floor and in the tire (© Klaus-Peter Möllmann and Michael Vollmer)

FIGURE 185 Thermometers: a mercury thermometer, an infrared thermometer, the ...in the skin, a liquid crystal thermometer, and the pit organ of a pit snake

gas, puts it in contact with the object, waits a while, and then measures the pressure and the volume of the gas. The ideal gas relation (94) then gives the temperature. Most importantly, the ideal gas relation shows that there is a lowest temperature in nature, namely that temperature at which an ideal gas would have a vanishing volume. That would happen at $T = 0\,\mathrm{K}$, i.e., at $-273.15\,^\circ\mathrm{C}$. Obviously, other effects, like the volume of the atoms themselves, prevent the volume of the gas from ever reaching zero. In fact, the unattainability of absolute zero is called the *third principle of thermodynamics*.

The temperature achieved by a civilization can be used as a measure of its technological achievements. One can define the Bronze Age (1.1 kK, 3500 BCE) , the Iron Age (1.8 kK, 1000 BCE), the Electric Age (3 kK from *c.* 1880) and the Atomic Age (several MK, from 1944) in this way. Taking into account also the quest for lower temperatures, one can define the Quantum Age (4 K, starting 1908). But what exactly is heating and cooling?

TABLE 41 Some temperature values

Observation	Temperature
Lowest, but unattainable, temperature	0 K = −273.15°C
In the context of lasers, it sometimes makes (almost) sense to talk about negative temperature.	
Temperature a perfect vacuum would have at Earth's surface Page 1207	40 zK
Sodium gas in certain laboratory experiments – coldest matter system achieved by man and possibly in the universe	0.45 nK
Temperature of neutrino background in the universe	*c.* 2 K
Temperature of photon gas background (or background radiation) in the universe	2.7 K
Liquid helium	4.2 K
Oxygen triple point	54.3584 K
Liquid nitrogen	77 K
Coldest weather ever measured (Antarctic)	185 K = −88°C
Freezing point of water at standard pressure	273.15 K = 0.00°C
Triple point of water	273.16 K = 0.01°C
Average temperature of the Earth's surface	287.2 K
Smallest uncomfortable skin temperature	316 K (10 K above normal)
Interior of human body	310.0 ± 0.5 K = 36.8 ± 0.5°C
Hottest weather ever measured	343.8 K = 70.7°C
Boiling point of water at standard pressure	373.13 K or 99.975°C
Large wood fire	*c.* 1100 K
Liquid bronze	*c.* 1100 K
Freezing point of gold	1337.33 K
Liquid, pure iron	1810 K
Bunsen burner flame	up to 1870 K
Light bulb filament	2.9 kK
Earth's centre	4 kK
Melting point of hafnium carbide	4.16 kK
Sun's surface	5.8 kK
Air in lightning bolt	30 kK
Hottest star's surface (centre of NGC 2240)	250 kK
Space between Earth and Moon (no typo)	up to 1 MK
Centre of white dwarf	5 to 20 MK
Sun's centre	20 MK
Centre of the accretion disk in X-ray binary stars	10 to 100 MK
Inside the JET fusion tokamak	100 MK
Centre of hottest stars	1 GK
Maximum temperature of systems without electron–positron pair generation	ca. 6 GK
Universe when it was 1 s old	100 GK
Hagedorn temperature	1.9 TK
Heavy ion collisions – highest man-made value	up to 3.6 TK
Planck temperature – nature's upper temperature limit	10^{32} K

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Thermal energy

Heating and cooling is the flow of disordered energy. For example, friction heats up and slows down moving bodies. In the old days, the 'creation' of heat by friction was even tested experimentally. It was shown that heat could be generated from friction, just by
Ref. 232 continuous rubbing, without any limit; an example is shown in Figure 184. This 'creation' implies that heat is not a material fluid extracted from the body – which in this case would be consumed after a certain time – but something else. Indeed, today we know that heat, even though it behaves in some ways like a fluid, is due to disordered motion of particles. The conclusion of these studies is simple. Friction is the transformation of mechanical (i.e., ordered) energy into (disordered) *thermal energy*.

To heat 1 kg of water by 1 K by friction, 4.2 kJ of mechanical energy must be transformed through friction. The first to measure this quantity with precision was, in 1842, the German physician Julius Robert Mayer (1814–1878). He regarded his experimenst as proofs of the conservation of energy; indeed, he was the first person to state energy conservation! It is something of an embarrassment to modern physics that a medical doctor was the first to show the conservation of energy, and furthermore, that he was ridiculed by most physicists of his time. Worse, conservation of energy was accepted by scientists only when it was repeated many years later by two authorities: Hermann von Helmholtz – himself also a physician turned physicist – and William Thomson, who also cited similar, but later experiments by James Joule.* All of them acknowledged Mayer's priority. Publicity by William Thomson eventually led to the naming of the unit of energy after Joule.

In short, the sum of mechanical energy and thermal energy is constant. This is usually called the *first principle of thermodynamics*. Equivalently, it is impossible to produce mechanical energy without paying for it with some other form of energy. This is an important statement, because among others it means that humanity will stop living one day. Indeed, we live mostly on energy from the Sun; since the Sun is of finite size, its energy
Challenge 527 s content will eventually be consumed. Can you estimate when this will happen?

There is also a second (and the mentioned third) principle of thermodynamics, which will be presented later on. The study of these topics is called *thermostatics* if the systems concerned are at equilibrium, and *thermodynamics* if they are not. In the latter case, we distinguish situations *near* equilibrium, when equilibrium concepts such as temperature can still be used, from situations *far* from equilibrium, such as self-organization, where
Page 302 such concepts often cannot be applied.

Does it make sense to distinguish between thermal energy and heat? It does. Many older texts use the term 'heat' to mean the same as thermal energy. However, this is confusing; in this text, 'heat' is used, in accordance with modern approaches, as the everyday term for entropy. Both thermal energy and heat flow from one body to another, and both accumulate. Both have no measurable mass.** Both the amount of thermal energy and

* Hermann von Helmholtz (b. 1821 Potsdam, d. 1894 Berlin), important Prussian scientist. William Thomson (later William Kelvin) (1824–1907), important Irish physicist. James Prescott Joule (1818–1889), English physicist. Joule is pronounced so that it rhymes with 'cool', as his descendants like to stress. (The pronunciation of the name 'Joule' varies from family to family.)

** This might change in future, when mass measurements improve in precision, thus allowing the detection
Page 443 of relativistic effects. In this case, temperature increase may be detected through its related mass increase.

TABLE 42 Some measured entropy values

Process / System	Entropy value
Melting of 1 kg of ice	1.21 kJ/K kg = 21.99 J/K mol
Water under standard conditions	70.1 J/K mol
Boiling of 1 kg of liquid water at 101.3 kPa	6.03 kJ/K= 110 J/K mol
Iron under standard conditions	27.2 J/K mol
Oxygen under standard conditions	161.1 J/K mol

the amount of heat inside a body increase with increasing temperature. The precise relation will be given shortly. But heat has many other interesting properties and stories to tell. Of these, two are particularly important: first, heat is due to particles; and secondly, heat is at the heart of the difference between past and future. These two stories are intertwined.

Entropy

> – It's irreversible.
> – Like my raincoat!
>
> Mel Brooks, *Spaceballs*, 1987

Every domain of physics describes change in terms of two quantities: energy, and an extensive quantity characteristic of the domain. Even though heat is related to energy, the quantity physicists usually call heat is *not* an extensive quantity. Worse, what physicists call heat is not the same as what we call heat in our everyday speech. The extensive quantity corresponding to what we call 'heat' in everyday speech is called *entropy* in physics.* Entropy describes heat in the same way as momentum describes motion. When two objects differing in temperature are brought into contact, an entropy flow takes place between them, like the flow of momentum that take place when two objects of different speeds collide. Let us define the concept of entropy more precisely and explore its properties in some more detail.

Ref. 228

Entropy measures the degree to which energy is *mixed up* inside a system, that is, the degree to which energy is spread or shared among the components of a system. When a lamb is transformed into minced meat, the entropy increases. Therefore, entropy *adds up* when identical systems are composed into one. When two one-litre bottles of water at the same temperature are poured together, the entropy of the water adds up. Entropy is thus an extensive quantity.

Like any other extensive quantity, entropy can be accumulated in a body; it can flow into or out of bodies. When water is transformed into steam, the entropy added into the water is indeed contained in the steam. In short, entropy is what is called 'heat' in everyday speech.

However, such changes are noticeable only with twelve or more digits of precision in mass measurements.

* The term 'entropy' was invented by the German physicist Rudolph Clausius (1822–1888) in 1865. He formed it from the Greek ἐν 'in' and τρόπος 'direction', to make it sound similar to 'energy'. It has always had the meaning given here.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In contrast to several other important extensive quantities, entropy is *not* conserved. The sharing of energy in a system can be increased, for example by heating it. However, entropy is 'half conserved': in closed systems, entropy never decreases; mixing cannot be undone. What is called equilibrium is simply the result of the highest possible mixing. In short, the entropy of a closed system increases until it reaches the maximum possible value.

When a piece of rock is detached from a mountain, it falls, tumbles into the valley, heating up a bit, and eventually stops. The opposite process, whereby a rock cools and tumbles upwards, is never observed. Why? The opposite motion does not contradict any rule or pattern about motion that we have deduced so far.

Challenge 528 ny

Rocks never fall upwards because mountains, valleys and rocks are made of many particles. Motions of many-particle systems, especially in the domain of thermostatics, are called *processes*. Central to thermostatics is the distinction between *reversible* processes, such as the flight of a thrown stone, and *irreversible* processes, such as the aforementioned tumbling rock. Irreversible processes are all those processes in which friction and its generalizations play a role. They are those which increase the sharing or mixing of energy. They are important: if there were no friction, shirt buttons and shoelaces would not stay fastened, we could not walk or run, coffee machines would not make coffee, and maybe most importantly of all, we would have no memory.

Ref. 233
Page 1088

Irreversible processes, in the sense in which the term is used in thermostatics, transform macroscopic motion into the disorganized motion of all the small microscopic components involved: they increase the sharing and mixing of energy. Irreversible processes are therefore not *strictly* irreversible – but their reversal is *extremely* improbable. We can say that entropy measures the 'amount of irreversibility': it measures the degree of mixing or decay that a collective motion has undergone.

Entropy is not conserved. Entropy – 'heat' – can appear out of nowhere, since energy sharing or mixing can happen by itself. For example, when two different liquids of the same temperature are mixed – such as water and sulphuric acid – the final temperature of the mix can differ. Similarly, when electrical current flows through material at room temperature, the system can heat up or cool down, depending on the material.

The *second principle of thermodynamics* states that 'entropy ain't what it used to be.' More precisely, *the entropy in a closed system tends towards its maximum*. Here, a *closed system* is a system that does not exchange energy or matter with its environment. Can you think of an example?

Challenge 529 ny

Entropy never decreases. Everyday life shows that in a closed system, the disorder increases with time, until it reaches some maximum. To reduce disorder, we need effort, i.e., work and energy. In other words, in order to reduce the disorder in a system, we need to connect the system to an energy source in some clever way. Refrigerators need electrical current precisely for this reason.

Because entropy never decreases, *white colour does not last*. Whenever disorder increases, the colour white becomes 'dirty', usually grey or brown. Perhaps for this reason white objects, such as white clothes, white houses and white underwear, are valued in our society. White objects defy decay.

Entropy allows to define the concept of *equilibrium* more precisely as the state of maximum entropy, or maximum energy sharing.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Flow of entropy

We know from daily experience that transport of an extensive quantity always involves friction. Friction implies generation of entropy. In particular, the flow of entropy itself produces additional entropy. For example, when a house is heated, entropy is produced in the wall. Heating means to keep a temperature difference ΔT between the interior and the exterior of the house. The heat flow J traversing a square metre of wall is given by

$$J = \kappa \Delta T = \kappa (T_\mathrm{i} - T_\mathrm{e}) \tag{95}$$

where κ is a constant characterizing the ability of the wall to conduct heat. While conducting heat, the wall also *produces* entropy. The entropy production σ is proportional to the difference between the interior and the exterior entropy flows. In other words, one has

$$\sigma = \frac{J}{T_\mathrm{e}} - \frac{J}{T_\mathrm{i}} = \kappa \frac{(T_\mathrm{i} - T_\mathrm{e})^2}{T_\mathrm{i} T_\mathrm{e}} \,. \tag{96}$$

Note that we have assumed in this calculation that everything is near equilibrium in each slice parallel to the wall, a reasonable assumption in everyday life. A typical case of a good wall has $\kappa = 1\,\mathrm{W/m^2K}$ in the temperature range between 273 K and 293 K. With this value, one gets an entropy production of

$$\sigma = 5 \cdot 10^{-3}\,\mathrm{W/m^2K} \,. \tag{97}$$

Challenge 530 ny

Can you compare the amount of entropy that is produced in the flow with the amount that is transported? In comparison, a good goose-feather duvet has $\kappa = 1.5\,\mathrm{W/m^2K}$, which in shops is also called 15 tog.*

Entropy can be transported in three ways: through *heat conduction*, as just mentioned, via *convection*, used for heating houses, and through *radiation*, which is possible also through empty space. For example, the Earth radiates about $1.2\,\mathrm{W/m^2K}$ into space, in total thus about 0.51 PW/K. The entropy is (almost) the same that the Earth receives from the Sun. If more entropy had to be radiated away than received, the temperature of the surface of the Earth would have to increase. This is called the *greenhouse effect* or *global warming*. Let's hope that it remains small in the near future.

Do isolated systems exist?

In all our discussions so far, we have assumed that we can distinguish the system under investigation from its environment. But do such *isolated* or *closed* systems, i.e., systems not interacting with their environment, actually exist? Probably our own human condition was the original model for the concept: we do experience having the possibility to

* That unit is not as bad as the official (not a joke) BthU · h/sqft/cm/°F used in some remote provinces of our galaxy.

The insulation power of materials is usually measured by the constant $\lambda = \kappa d$ which is independent of the thickness d of the insulating layer. Values in nature range from about 2000 W/K m for diamond, which is the best conductor of all, down to between 0.1 W/K m and 0.2 W/K m for wood, between 0.015 W/K m and 0.05 W/K m for wools, cork and foams, and the small value of $5 \cdot 10^{-3}$ W/K m for krypton gas.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

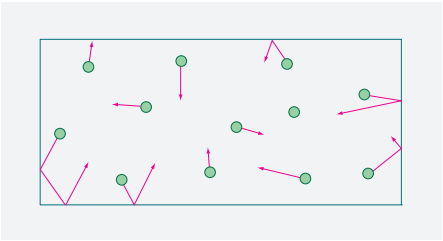

FIGURE 186 The basic idea of statistical mechanics about gases

FIGURE 187 What happened here? (© Johan de Jong)

act independently of our environment. An isolated system may be simply defined as a system not exchanging any energy or matter with its environment. For many centuries, scientists saw no reason to question this definition.

The concept of an isolated system had to be refined somewhat with the advent of quantum mechanics. Nevertheless, the concept provides useful and precise descriptions of nature also in that domain. Only in the final part of our walk will the situation change drastically. There, the investigation of whether the universe is an isolated system will lead to surprising results. (What do you think?)* We'll take the first steps towards the answer shortly.

Challenge 531 s

Why do balloons take up space? – The end of continuity

Heat properties are material-dependent. Studying them should therefore enable us to understand something about the constituents of matter. Now, the simplest materials of all are gases.** Gases need space: an amount of gas has pressure and volume. Indeed, it did

* A strange hint: your answer is almost surely wrong.

** By the way, the word *gas* is a modern construct. It was coined by the Brussels alchemist and physician Johan Baptista van Helmont (1579–1644), to sound similar to 'chaos'. It is one of the few words which have been invented by one person and then adopted all over the world.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

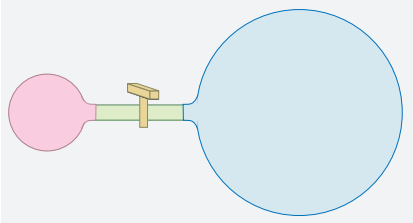

FIGURE 188 Which balloon wins when the tap is opened?

not take long to show that gases *could not* be continuous. One of the first scientists to think about gases as made up of atoms was Daniel Bernoulli. Bernoulli reasoned that if atoms are small particles, with mass and momentum, he should be able to make quantitative predictions about the behaviour of gases, and check them with experiment. If the particles fly around in a gas, then the *pressure* of a gas in a container is produced by the steady flow of particles hitting the wall. It was then easy to conclude that if the particles are assumed to behave as tiny, hard and perfectly elastic balls, the pressure p, volume V and temperature T must be related by

Challenge 532 ny

$$pV = kNT \tag{98}$$

where N is the number of particles contained in the gas. (The Boltzmann constant k, one of the fundamental constants of nature, is defined below.) A gas made of particles with such textbook behaviour is called an *ideal gas*. Relation (98) has been confirmed by experiments at room and higher temperatures, for all known gases.

Bernoulli thus derived the gas relation, with a specific prediction for the proportionality constant, from the single assumption that gases are made of small massive constituents. This derivation provides a clear argument for the existence of atoms and for their behaviour as normal, though small objects. (Can you imagine how N might be determined experimentally?)

Challenge 533 ny

The ideal gas model helps us to answer questions such as the one illustrated in Figure 188. Two *identical* rubber balloons, one filled up to a larger size than the other, are connected via a pipe and a valve. The valve is opened. Which one deflates?

Challenge 534 s

The ideal gas relation states that hotter gases, at given pressure, need more volume. The relation thus explains why winds and storms exist, why hot air balloons rise, why car engines work, why the ozone layer is destroyed by certain gases, or why during the extremely hot summer of 2001 in the south of Turkey, oxygen masks were necessary to walk outside during the day.

Challenge 535 e

Now you can also take up the following challenge: how can you measure the weight of a car or a bicycle with a ruler only?

Challenge 536 s

The picture of gases as being made of hard constituents without any long-distance interactions breaks down at very low temperatures. However, the ideal gas relation (98) can be improved to overcome these limitations by taking into account the deviations due to interactions between atoms or molecules. This approach is now standard practice and allows us to measure temperatures even at extremely low values. The effects observed below 80 K, such as the solidification of air, frictionless transport of electrical current, or

Ref. 234

Ref. 235

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Page 1170, page 1176

frictionless flow of liquids, form a fascinating world of their own, the beautiful domain of low-temperature physics; it will be explored later on.

Challenge 537 e

You are now able to explain why balloons change in size as they rise high up in the atmosphere. The largest balloon built so far had a diameter, at high altitude, of 170 m, but only a fraction of that value at take-off.

Brownian motion

If fluids are made of particles moving randomly, this random motion should have observable effects. Indeed, under a microscope it is easy to observe that small particles (such as pollen) in a liquid never come to rest. An example is shown in Figure 189. The pollen particles seem to follow a random zigzag movement. In 1827, the English botanist Robert Brown (1773–1858) showed with a series of experiments that this observation is independent of the type of particle and of the type of liquid. In other words, Brown had discovered a fundamental form of *noise* in nature. Around 1860, this motion was attributed to the molecules of the liquid colliding with the particles. In 1905 and 1906, Marian von Smoluchowski and, independently, Albert Einstein argued that this attribution could be tested experimentally, even though at that time nobody was able to observe molecules directly. The test makes use of the specific properties of thermal noise.

Ref. 236

It had already been clear for a long time that if molecules, i.e., indivisible matter particles, really existed, then thermal energy had to be disordered motion of these constituents and temperature had to be the average energy per degree of freedom of the constituents. Bernoulli's model of Figure 186 implies that for monatomic gases the kinetic energy T_{kin} per particle is given by

Challenge 538 ny

$$T_{\text{kin}} = \frac{3}{2} k T \tag{99}$$

where T is temperature. The so-called *Boltzmann constant* $k = 1.4 \cdot 10^{-23}\,\text{J/K}$ is the standard conversion factor between temperature and energy.* At a room temperature of 293 K, the kinetic energy is thus 6 zJ.

Challenge 539 e

Using relation (99) to calculate the speed of air molecules at room temperature yields values of several hundred metres per second. Given this large speed, why does smoke from a candle take so long to diffuse through a room? Rudolph Clausius (1822–1888) answered this question in the mid-nineteenth century: smoke diffusion is slowed by the collisions with air molecules, in the same way as pollen particles collide with molecules in liquids.

At first sight, one could guess that the average distance the pollen particle has moved after n collisions should be zero, because the molecule velocities are random. However,

* The Boltzmann constant k was discovered and named by Max Planck, in the same work in which he also discovered what is now called Planck's constant $\hbar$, the quantum of action. For more details on Max Planck, see page 768.

Planck named the Boltzmann constant after the important Austrian physicist Ludwig Boltzmann (b. 1844 Vienna, d. 1906 Duino), who is most famous for his work on thermodynamics. Boltzmann he explained all thermodynamic phenomena and observables, above all entropy itself, as results of the behaviour of molecules. It is said that Boltzmann committed suicide partly because of the animosities of his fellow physicists towards his ideas and himself. Nowadays, his work is standard textbook material.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

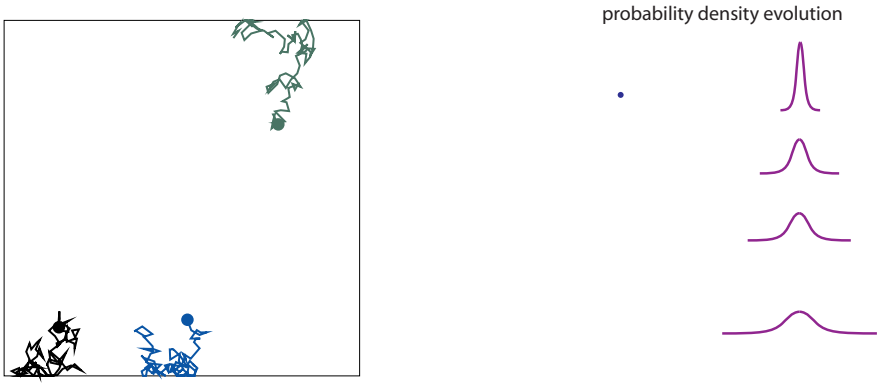

FIGURE 189 Example paths for particles in Brownian motion and their displacement distribution

this is wrong, as experiment shows.

An increasing average *square* displacement, written $\langle d^2 \rangle$, is observed for the pollen particle. It cannot be predicted in which direction the particle will move, but it does move. If the distance the particle moves after one collision is l, the average square displacement after n collisions is given, as you should be able to show yourself, by

Challenge 540 ny

$$\langle d^2 \rangle = nl^2 \,. \tag{100}$$

For molecules with an average velocity v over time t this gives

$$\langle d^2 \rangle = nl^2 = vlt \,. \tag{101}$$

In other words, the average square displacement increases proportionally with time. Of course, this is only valid because the liquid is made of separate molecules. Repeatedly measuring the position of a particle should give the distribution shown in Figure 189 for the probability that the particle is found at a given distance from the starting point. This is called the *(Gaussian) normal distribution*. In 1908, Jean Perrin* performed extensive experiments in order to test this prediction. He found that equation (101) corresponded completely with observations, thus convincing everybody that Brownian motion is indeed due to collisions with the molecules of the surrounding liquid, as had been expected.** Perrin received the 1926 Nobel Prize for these experiments.

Ref. 237

Einstein also showed that the same experiment could be used to determine the number of molecules in a litre of water (or equivalently, the Boltzmann constant k). Can you work out how he did this?

Challenge 541 d

* Jean Perrin (1870–1942), important French physicist, devoted most of his career to the experimental proof of the atomic hypothesis and the determination of Avogadro's number; in pursuit of this aim he perfected the use of emulsions, Brownian motion and oil films. His Nobel Prize speech (nobelprize.org/physics/laureates/1926/perrin-lecture.html) tells the interesting story of his research. He wrote the influential book *Les atomes* and founded the Centre National de la Recherche Scientifique. He was also the first to speculate, in 1901, that an atom is similar to a small solar system.

** In a delightful piece of research, Pierre Gaspard and his team showed in 1998 that Brownian motion is also chaotic, in the strict physical sense given later on.

TABLE 43 Some typical entropy values per particle at *standard* temperature and pressure as multiples of the Boltzmann constant

Material	Entropy per particle
Monatomic solids	0.3 k to 10 k
Diamond	0.29 k
Graphite	0.68 k
Lead	7.79 k
Monatomic gases	15-25 k
Helium	15.2 k
Radon	21.2 k
Diatomic gases	15 k to 30 k
Polyatomic solids	10 k to 60 k
Polyatomic liquids	10 k to 80 k
Polyatomic gases	20 k to 60 k
Icosane	112 k

Entropy and particles

Once it had become clear that heat and temperature are due to the motion of microscopic particles, people asked what entropy *was* microscopically. The answer can be formulated in various ways. The two most extreme answers are:

— Entropy is the expected number of yes-or-no questions, multiplied by $k \ln 2$, the answers of which would tell us everything about the system, i.e., about its microscopic state.
— Entropy measures the (logarithm of the) number W of possible microscopic states. A given macroscopic state can have many microscopic realizations. The logarithm of this number, multiplied by the Boltzmann constant k, gives the entropy.*

In short, the higher the entropy, the more microstates are possible. Through either of these definitions, entropy measures the quantity of randomness in a system. In other words, it measures the transformability of energy: higher entropy means lower transformability. Alternatively, entropy measures the *freedom* in the choice of microstate that a system has. High entropy means high freedom of choice for the microstate. For example, when a molecule of glucose (a type of sugar) is produced by photosynthesis, about 40 bits of entropy are released. This means that after the glucose is formed, 40 additional yes-or-no questions must be answered in order to determine the full microscopic state of the system. Physicists often use a macroscopic unit; most systems of interest are large, and thus an entropy of 10^{23} bits is written as 1 J/K. (This is only approximate. Can you find the precise value?)

Challenge 542 ny

* When Max Planck went to Austria to search for the anonymous tomb of Boltzmann in order to get him buried in a proper grave, he inscribed the formula $S = k \ln W$ on the tombstone. (Which physicist would

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

To sum up, entropy is thus a specific measure for the characterization of disorder of thermal systems. Three points are worth making here. First of all, entropy is not *the* measure of disorder, but *one* measure of disorder. It is therefore *not* correct to use entropy as a *synonym* for the concept of disorder, as is often done in the popular literature. Entropy is only defined for systems that have a temperature, in other words, only for systems that are in or near equilibrium. (For systems far from equilibrium, no measure of disorder has been found yet; probably none is possible.) In fact, the use of the term entropy has degenerated so much that sometimes one has to call it *thermodynamic* entropy for clarity.

Ref. 239

Secondly, entropy is related to information *only if* information is defined also as $-k \ln W$. To make this point clear, take a book with a mass of one kilogram. At room temperature, its entropy content is about 4 kJ/K. The printed information inside a book, say 500 pages of 40 lines with each containing 80 characters out of 64 possibilities, corresponds to an entropy of $4 \cdot 10^{-17}$ J/K. In short, what is usually called 'information' in everyday life is a negligible fraction of what a physicist calls information. Entropy is defined using the *physical* concept of information.

Finally, entropy is also *not* a measure for what in normal life is called the *complexity* of a situation. In fact, nobody has yet found a quantity describing this everyday notion. The task is surprisingly difficult. Have a try!

Ref. 240

Challenge 543 ny

In summary, if you hear the term entropy used with a different meaning than $S = k \ln W$, beware. Somebody is trying to get you, probably with some ideology.

The minimum entropy of nature – the quantum of information

Before we complete our discussion of thermostatics we must point out in another way the importance of the Boltzmann constant k. We have seen that this constant appears whenever the granularity of matter plays a role; it expresses the fact that matter is made of small basic entities. The most striking way to put this statement is the following: *There is a smallest entropy in nature.* Indeed, for all systems, the entropy obeys

$$S \geqslant \frac{k}{2} \,. \tag{102}$$

This result is almost 100 years old; it was stated most clearly (with a different numerical factor) by the Hungarian–German physicist Leo Szilard. The same point was made by the French physicist Léon Brillouin (again with a different numerical factor). The statement can also be taken as the *definition* of the Boltzmann constant.

Ref. 241

Ref. 242

The existence of a smallest entropy in nature is a strong idea. It eliminates the possibility of the continuity of matter and also that of its fractality. A smallest entropy implies that matter is made of a finite number of small components. The limit to entropy expresses the fact that matter is made of particles.* The limit to entropy also shows that Galilean physics cannot be correct: Galilean physics assumes that arbitrarily small quantities do exist. The entropy limit is the first of several limits to motion that we will encounter until

finance the tomb of another, nowadays?)

* The minimum entropy implies that matter is made of tiny spheres; the minimum *action*, which we will encounter in quantum theory, implies that these spheres are actually small clouds.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

we complete the quantum part of our ascent. After we have found all limits, we can start the final part, leading to unification.

The existence of a smallest quantity implies a limit on the precision of measurement. Measurements cannot have infinite precision. This limitation is usually stated in the form of an indeterminacy relation. Indeed, the existence of a smallest entropy can be rephrased as an indeterminacy relation between the temperature T and the inner energy U of a system:

$$\Delta\frac{1}{T}\,\Delta U \geqslant \frac{k}{2}\,. \tag{103}$$

Ref. 244 This relation* was given by Niels Bohr; it was discussed by Werner Heisenberg, who Page 1470 called it one of the basic indeterminacy relations of nature. The Boltzmann constant (di- Ref. 245 vided by 2) thus fixes the smallest possible entropy value in nature. For this reason, Gilles Ref. 242 Cohen-Tannoudji calls it the *quantum of information* and Herbert Zimmermann calls it the *quantum of entropy*.

The relation (103) points towards a more general pattern. For every minimum value for an observable, there is a corresponding indeterminacy relation. We will come across this several times in the rest of our adventure, most importantly in the case of the quan- Page 976 tum of action and Heisenberg's indeterminacy relation.

The existence of a smallest entropy has numerous consequences. First of all, it sheds light on the third principle of thermodynamics. A smallest entropy implies that absolute zero temperature is not achievable. Secondly, a smallest entropy explains why entropy values are finite instead of infinite. Thirdly, it fixes the absolute value of entropy for every system; in continuum physics, entropy, like energy, is only defined up to an additive constant. The entropy limit settles all these issues.

The existence of a minimum value for an observable implies that an indeterminacy relation appears for any two quantities whose product yields that observable. For example, entropy production rate and time are such a pair. Indeed, an indeterminacy relation connects the entropy production rate $P = \mathrm{d}S/\mathrm{d}t$ and the time t:

$$\Delta P\,\Delta t \geqslant \frac{k}{2}\,. \tag{104}$$

From this and the previous relation (103) it is possible to deduce all of statistical physics, Ref. 245, Ref. 243 i.e., the precise theory of thermostatics and thermodynamics. We will not explore this further here. (Can you show that the zeroth and third principle follows from the existence Challenge 544 ny of a smallest entropy?) We will limit ourselves to one of the cornerstones of thermodynamics: the second principle.

Why can't we remember the future?

> It's a poor sort of memory which only works backwards.
>
> Lewis Carroll, *Alice in Wonderland*

Ref. 243 * It seems that the historical value for the right hand side, given by k, has to be corrected to $k/2$.

TABLE 44 Some minimum flow values found in nature

Observation	Minimum value
Matter flow	one molecule or one atom or one particle
Volume flow	one molecule or one atom or one particle
Momentum flow	Planck's constant divided by wavelength
Angular momentum flow	Planck's constant
Chemical amount of substance	one molecule, one atom or one particle
Entropy flow	minimum entropy
Charge flow	elementary charge
Light flow	Planck's constant divided by wavelength

Page 45 When we first discussed time, we ignored the difference between past and future. But obviously, a difference exists, as we do not have the ability to remember the future. This is not a limitation of our brain alone. All the devices we have invented, such as tape recorders, photographic cameras, newspapers and books, only tell us about the past. Is there a way to build a video recorder with a 'future' button? Such a device would have to Challenge 545 ny solve a deep problem: how would it distinguish between the near and the far future? It does not take much thought to see that any way to do this would conflict with the second principle of thermodynamics. That is unfortunate, as we would need precisely the same Challenge 546 ny device to show that there is faster-than-light motion. Can you find the connection?

In summary, the future cannot be remembered because entropy in closed systems tends towards a maximum. Put even more simply, memory exists because the brain is made of many particles, and so the brain is limited to the past. However, for the most simple types of motion, when only a few particles are involved, the difference between past and future disappears. For few-particle systems, there is no difference between times gone by and times approaching. We could say that the future differs from the past only in our brain, or equivalently, only because of friction. Therefore the difference between the past and the future is not mentioned frequently in this walk, even though it is an essential part of our human experience. But the fun of the present adventure is precisely to overcome our limitations.

Is everything made of particles?

> A physicist is the atom's way of knowing about atoms.
>
> George Wald

Ref. 246

Historically, the study of statistical mechanics has been of fundamental importance for physics. It provided the first demonstration that physical objects are made of interacting particles. The story of this topic is in fact a long chain of arguments showing that all the properties we ascribe to objects, such as size, stiffness, colour, mass density, magnetism, thermal or electrical conductivity, result from the interaction of the many particles they consist of. The discovery that *all objects are made of interacting particles* has often been called the main result of modern science.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

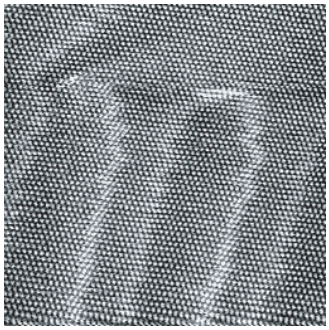

FIGURE 190 A 111 surface of a gold single crystal, every bright dot being an atom, with a surface dislocation (© CNRS)

Page 277

How was this discovery made? Table 40 listed the main extensive quantities used in physics. Extensive quantities are able to flow. It turns out that all flows in nature are *composed* of elementary processes, as shown in Table 44. We have seen that the flow of mass, volume, charge, entropy and substance are composed. Later, quantum theory will show the same for the flow of linear and angular momentum. *All flows are made of particles.*

This success of this idea has led many people to generalize it to the statement: 'Everything we observe is made of parts.' This approach has been applied with success to chemistry with molecules, materials science and geology with crystals, electricity with electrons, atoms with elementary particles, space with points, time with instants, light with photons, biology with cells, genetics with genes, neurology with neurons, mathematics with sets and relations, logic with elementary propositions, and even to linguistics with morphemes and phonemes. All these sciences have flourished on the idea that everything is made of related *parts*. The basic idea seems so self-evident that we find it difficult even to formulate an alternative. Just try!

Ref. 247

Challenge 547 ny

However, in the case of the *whole* of nature, the idea that nature is a sum of related parts is incorrect. It turns out to be a prejudice, and a prejudice so entrenched that it retarded further developments in physics in the latter decades of the twentieth century. In particular, it does *not* apply to elementary particles or to space-time. Finding the correct description for the whole of nature is the biggest challenge of our adventure, as it requires a complete change in thinking habits. There is a lot of fun ahead.

Page 1440

Why stones can be neither smooth nor fractal, nor made of little hard balls

The exploration of temperature yields another interesting result. Researchers first studied gases, and measured how much energy was needed to heat them by 1 K. The result

* 'Every statement about complexes can be resolved into a statement about their constituents and into the propositions that describe the complexes completely.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

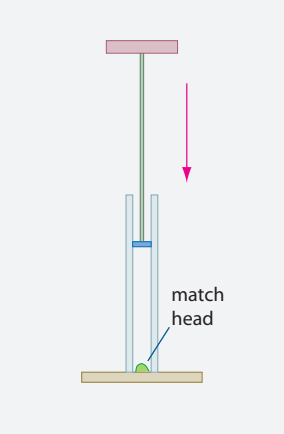

FIGURE 191 The fire pump

is simple: all gases share only a few values, when the number of molecules N is taken into account. Monatomic gases (in a container with constant volume) require $3Nk/2$, diatomic gases (and those with a linear molecule) $5Nk/2$, and almost all other gases $3Nk$, where $k = 1.4 \cdot 10^{-23}$ J/K is the Boltzmann constant.

Page 287

The explanation of this result was soon forthcoming: each thermodynamic degree of freedom* contributes the energy $kT/2$ to the total energy, where T is the temperature. So the number of degrees of freedom in physical bodies is finite. Bodies are not continuous, nor are they fractals: if they were, their specific thermal energy would be infinite. Matter is indeed made of small basic entities.

All degrees of freedom contribute to the specific thermal energy. At least, this is what classical physics predicts. Solids, like stones, have 6 thermodynamic degrees of freedom and should show a specific thermal energy of $3Nk$. At high temperatures, this is indeed observed. But measurements of solids at room temperature yield lower values, and the lower the temperature, the lower the values become. Even gases show values lower than those just mentioned, when the temperature is sufficiently low. In other words, molecules and atoms behave differently at low energies: atoms are not immutable little hard balls. The deviation of these values is one of the first hints of quantum theory.

Curiosities and fun challenges about heat and reversibility

Compression of air increases its temperature. This is shown directly by the fire pump, a variation of a bicycle pump, shown in Figure 191. (For a working example, see the website www.tn.tudelft.nl/cdd). A match head at the bottom of an air pump made of transparent material is easily ignited by the compression of the air above it. The temperature of the air after compression is so high that the match head ignites spontaneously.

* A *thermodynamic degree of freedom* is, for each particle in a system, the number of dimensions in which it can move plus the number of dimensions in which it is kept in a potential. Atoms in a solid have six, particles in monatomic gases have only three; particles in diatomic gases or rigid linear molecules have five. The number of degrees of freedom of larger molecules depends on their shape.

If heat really is disordered motion of atoms, a big problem appears. When two atoms collide head-on, in the instant of smallest distance, neither atom has velocity. Where does the kinetic energy go? Obviously, it is transformed into potential energy. But that implies that atoms can be deformed, that they have internal structure, that they have parts, and thus that they can in principle be split. In short, if heat is disordered atomic motion, *atoms are not indivisible*! In the nineteenth century this argument was put forward in order to show that heat cannot be atomic motion, but must be some sort of fluid. But since we know that heat really is kinetic energy, atoms must indeed be divisible, even though their name means 'indivisible'. We do not need an expensive experiment to show this.

* *

Ref. 249 In 1912, Emile Borel noted that if a gram of matter on Sirius was displaced by one centimetre, it would change the gravitational field on Earth by a tiny amount only. But this tiny change would be sufficient to make it impossible to calculate the path of molecules in a gas after a fraction of a second.

* *

Not only gases, but also most other materials expand when the temperature rises. As a result, the electrical wires supported by pylons hang much lower in summer than in winter. True? Challenge 549 s

* *

One gram of fat, either butter or human fat, contains 38 kJ of chemical energy (or, in ancient units more familiar to nutritionists, 9 kcal). That is the same value as that of petrol. Challenge 557 s Why are people and butter less dangerous than petrol?

* *

In 1992, the Dutch physicist Martin van der Mark invented a loudspeaker which works by heating air with a laser beam. He demonstrated that with the right wavelength and with a suitable modulation of the intensity, a laser beam in air can generate sound. The effect at the basis of this device, called the *photoacoustic effect*, appears in many materials. The best laser wavelength for air is in the infrared domain, on one of the few absorption lines of water vapour. In other words, a properly modulated infrared laser beam that shines through the air generates sound. Such light can be emitted from a small matchbox-sized semiconductor laser hidden in the ceiling and shining downwards. The sound is emitted in all directions perpendicular to the beam. Since infrared laser light is not visible, Martin van der Mark thus invented an invisible loudspeaker! Unfortunately, the efficiency of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

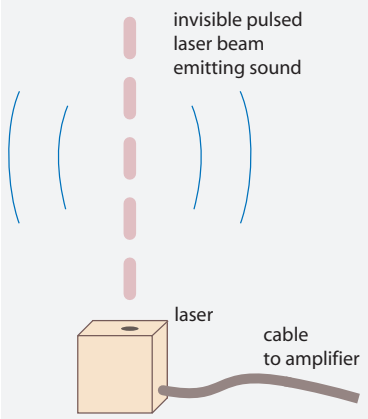

FIGURE 193 The invisible loudspeaker

present versions is still low, so that the power of the speaker is not yet sufficient for practical applications. Progress in laser technology should change this, so that in the future we should be able to hear sound that is emitted from the centre of an otherwise empty room.

If you pour a litre of water into the sea, stir thoroughly through all the oceans and then
Challenge 565 ny take out a litre of the mixture, how many of the original atoms will you find?

* *

Challenge 566 ny How long would you go on breathing in the room you are in if it were airtight?

* *

Challenge 567 ny What happens if you put some ash onto a piece of sugar and set fire to the whole? (Warning: this is dangerous and not for kids.)

* *

Entropy calculations are often surprising. For a system of N particles with two states each, there are $W_{\text{all}} = 2^N$ states. For its most probable configuration, with exactly half the particles in one state, and the other half in the other state, we have $W_{\text{max}} = N!/((N/2)!)^2$. Now, for a macroscopic system of particles, we might typically have $N = 10^{24}$. That gives $W_{\text{all}} \gg W_{\text{max}}$; indeed, the former is 10^{12} times larger than the latter. On the other hand,
Challenge 568 ny we find that $\ln W_{\text{all}}$ and $\ln W_{\text{max}}$ agree for the first 20 digits! Even though the configuration with exactly half the particles in each state is much more rare than the general case,
Challenge 569 ny where the ratio is allowed to vary, the entropy turns out to be the same. Why?

There are less-well known arguments about atoms. In fact, two everyday prove the existence of atoms: sex and memory. Why? Challenge 584 ny

In the context of lasers and of spin systems, it is fun to talk about negative temperature.

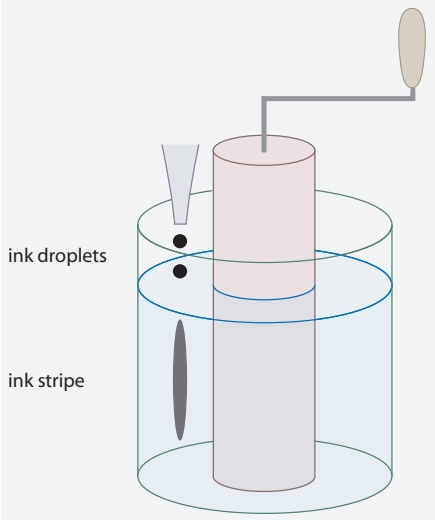

FIGURE 195 What happens to the ink stripe if the inner cylinder is turned a few times in one direction, and then turned back by the same amount?

Challenge 585 s Why is this not really sensible?

Summary on heat and time-invariance

Microscopic motion due to gravity and electric interactions, thus all microscopic motion in everyday life, is *reversible*: such motion can occur backwards in time. In other words, motion due to gravity and electromagnetism is time-reversal-invariant or motion-reversal-invariant.

Nevertheless, everyday motion is *irreversible*, because there are no completely closed systems in everyday life. Equivalently, irreversibility results from the extremely low probabilities required to perform a motion inversion. Macroscopic irreversibility does not contradict microscopic reversibility.

For these reasons, in everyday life, entropy in closed systems always increases. This leads to a famous issue: how can evolution be reconciled with entropy increase? Let us have a look.

Chapter 13

SELF-ORGANIZATION AND CHAOS – THE SIMPLICITY OF COMPLEXITY

> To speak of non-linear physics is like calling zoology the study of non-elephant animals.
>
> Stanislaw Ulam

Ref. 254

In our list of global descriptions of motion, the high point is the study of self-organization. Self-organization is the appearance of order. *Order* is a term that includes *shapes*, such as the complex symmetry of snowflakes; *patterns*, such as the stripes of zebras; and *cycles*, such as the creation of sound when singing. Indeed, every example of what we call *beauty* is a combination of shapes, patterns and cycles. (Do you agree?) Self-organization can thus be called the study of the origin of beauty.

Ref. 255

Challenge 586 s

The appearance of order is a general observation across nature. Fluids in particular exhibit many phenomena where order appears and disappears. Examples include the more or less regular flickering of a burning candle, the flapping of a flag in the wind, the regular stream of bubbles emerging from small irregularities in the surface of a champagne glass, and the regular or irregular dripping of a water tap.

The appearance of order is found from the cell differentiation in an embryo inside a woman's body; the formation of colour patterns on tigers, tropical fish and butterflies; the symmetrical arrangements of flower petals; the formation of biological rhythms; and so on.

All growth processes are self-organization phenomena. Have you ever pondered the incredible way in which teeth grow? A practically inorganic material forms shapes in the upper and the lower rows fitting exactly into each other. How this process is controlled is still a topic of research. Also the formation, before and after birth, of neural networks in the brain is another process of self-organization. Even the physical processes at the basis of thinking, involving changing electrical signals, is to be described in terms of self-organization.

Page 794

Biological evolution is a special case of growth. Take the evolution of animal shapes. It turns out that snake tongues are forked because that is the most efficient shape for following chemical trails left by prey and other snakes of the same species. (Snakes smell with help of the tongue.) The fixed numbers of fingers in human hands or of petals of flowers are also consequences of self-organization.

Ref. 256

Page 948

Many problems of self-organization are mechanical problems: for example, the formation of mountain ranges when continents move, the creation of earthquakes, or the creation of regular cloud arrangements in the sky. It can be fascinating to ponder, during an otherwise boring flight, the mechanisms behind the formation of the clouds you see

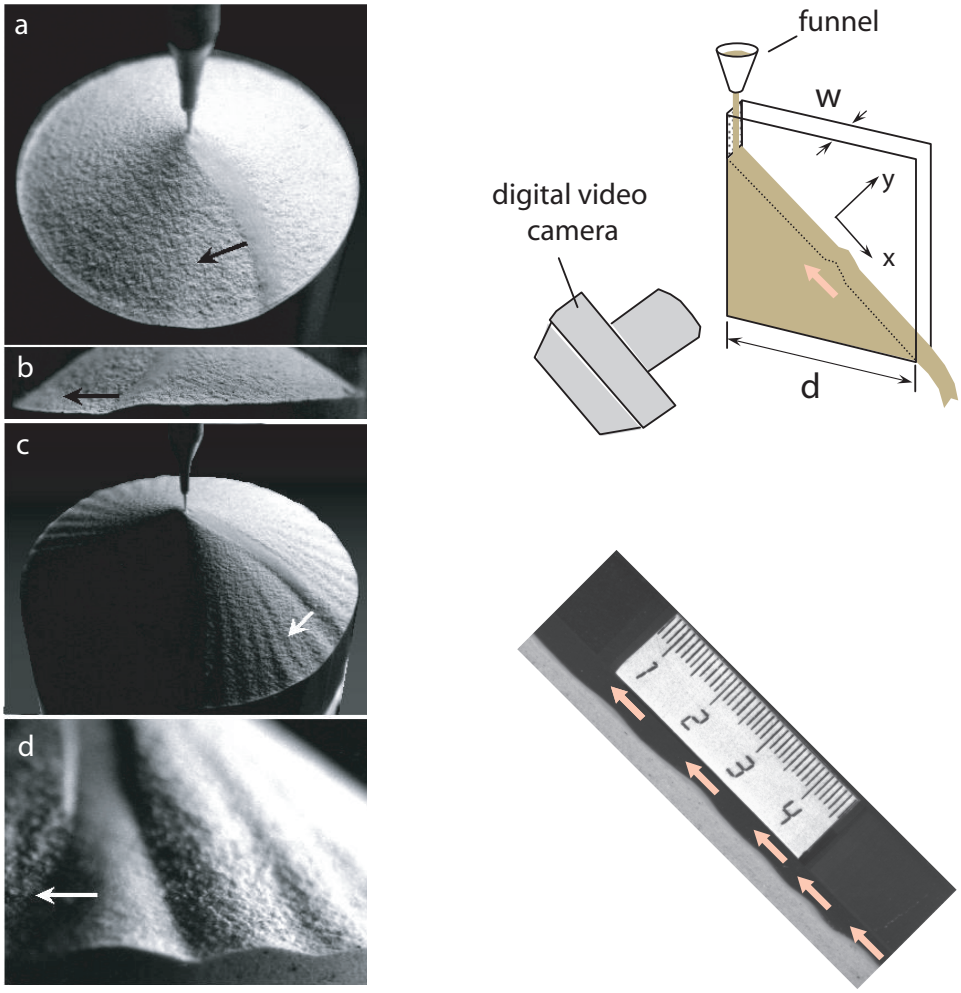

FIGURE 196 Examples of self-organization for sand: spontaneous appearance of a temporal cycle (a and b), spontaneous appearance of a periodic pattern (b and c), spontaneous appearance of a spatiotemporal pattern, namely solitary waves (right) (© Ernesto Altshuler et al.)

Challenge 587 e from the aeroplane.

Studies into the conditions required for the appearance or disappearance of order have shown that their description requires only a few common concepts, independently of the details of the physical system. This is best seen looking at a few examples.

All the richness of self-organization reveals itself in the study of plain sand. Why do sand dunes have ripples, as does the sand floor at the bottom of the sea? We can also study how avalanches occur on steep heaps of sand and how sand behaves in hourglasses, in mixers, or in vibrating containers. The results are often surprising. For example, as recently as 2006, the Cuban research group of Ernesto Altshuler and his colleagues Ref. 257 discovered solitary waves on sand flows (shown in Figure 196). They had already discov-

On Mars	a few km	few tens of m	wind

FIGURE 197 Road corrugations (courtesy David Mays)

ered the revolving river effect on sand piles, shown in the same figure, in 2002. Even more surprisingly, these effects occur only for Cuban sand, and a few rare other types of sand. The reasons are still unknown.

Ref. 258 Similarly, in 1996 Paul Umbanhowar and his colleagues found that when a flat container holding tiny bronze balls (around 0.165 mm in diameter) is shaken up and down in vacuum at certain frequencies, the surface of this bronze 'sand' forms stable heaps. They are shown in Figure 198. These heaps, so-called *oscillons*, also bob up and down. Oscillons can move and interact with one another.

Oscillons in sand are a simple example for a general effect in nature: *discrete* systems with nonlinear interactions can exhibit localized excitations. This fascinating topic is just Ref. 259 beginning to be researched. It might well be that it will yield results relevant to our understanding of elementary particles.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 198 Oscillons formed by shaken bronze balls; horizontal size is about 2 cm (© Paul Umbanhowar)

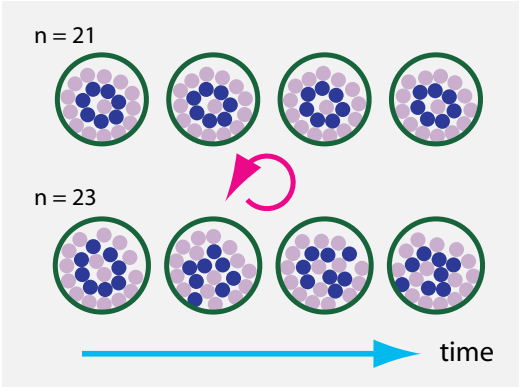

FIGURE 199 Magic numbers: 21 spheres, when swirled in a dish, behave differently from non-magic numbers, like 23, of spheres (redrawn from photographs, © Karsten Kötter)

Sand shows many other pattern-forming processes. A mixture of sand and sugar, when poured onto a heap, forms regular layered structures that in cross section look like zebra stripes. Horizontally rotating cylinders with binary mixtures inside them separate the mixture out over time. Or take a container with two compartments separated by a 1 cm wall. Fill both halves with sand and rapidly shake the whole container with a machine. Over time, all the sand will spontaneously accumulate in one half of the container. As another example of self-organization in sand, people have studied the various types of sand dunes that 'sing' when the wind blows over them. Finally, the corrugations formed by traffic on roads without tarmac are an example of self-organization that is not completely explored; it is still unclear, for example, why these corrugation patterns move against the traffic direction over time. (Can you find out?) In fact, the behaviour of sand and dust is proving to be such a beautiful and fascinating topic that the prospect of each human returning dust does not look so grim after all.

Ref. 260

Ref. 261

Another simple and beautiful example of self-organization is the effect discovered in 1999 by Karsten Kötter and his group. They found that the behaviour of a set of spheres swirled in a dish depends on the number of spheres used. Usually, all the spheres get continuously mixed up. But for certain 'magic' numbers, such as 21, stable ring patterns emerge, for which the outside spheres remain outside and the inside ones remain inside. The rings, best seen by colouring the spheres, are shown in Figure 199.

Ref. 262

These and many other studies of self-organizing systems have changed our understanding of nature in a number of ways. First of all, they have shown that patterns and shapes are similar to cycles: all are due to motion. Without motion, and thus without history, there is no order, neither patterns nor shapes. Every pattern has a history; every pattern is a result of motion. An example is shown in Figure 200.

Ref. 263

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 200 Self-organization: a growing snow flake (QuickTime film © Kenneth Libbrecht)

Secondly, patterns, shapes and cycles are due to the organized motion of large numbers of small constituents. Systems which self-organize are always composite: they are *cooperative structures*.

Thirdly, all these systems obey evolution equations which are *nonlinear* in the configuration variables. Linear systems do not self-organize. Many self-organizing systems also show *chaotic* motion.

Fourthly, the appearance and disappearance of order depends on the strength of a driving force, the so-called *order parameter*. Often, chaotic motion appears when the driving is increased beyond the value necessary for the appearance of order. An example of chaotic motion is turbulence, which appears when the order parameter, which is proportional to the speed of the fluid, is increased to high values.

Moreover, all order and all structure appears when two general types of motion compete with each other, namely a 'driving', energy-adding process, and a 'dissipating', braking mechanism. Thermodynamics plays a role in all self-organization. Self-organizing systems are always *dissipative systems*, and are always far from equilibrium. When the driving and the dissipation are of the same order of magnitude, and when the key behaviour of the system is not a linear function of the driving action, order may appear.*

All self-organizing systems at the onset of order appearance can be described by equations for the pattern amplitude A of the general form

$$\frac{\partial A(t,x)}{\partial t} = \lambda A - \mu |A|^2 A + \kappa \, \Delta A + \text{higher orders} \,. \tag{105}$$

Here, the – possibly complex – observable A is the one that appears when order appears,

* To describe the 'mystery' of human life, terms like 'fire', 'river' or 'tree' are often used as analogies. These are all examples of self-organized systems: they have many degrees of freedom, have competing driving and braking forces, depend critically on their initial conditions, show chaos and irregular behaviour, and sometimes show cycles and regular behaviour. Humans and human life resemble them in all these respects; thus there is a solid basis to their use as metaphors. We could even go further and speculate that pure beauty *is* pure self-organization. The lack of beauty indeed often results from a disturbed equilibrium between external braking and external driving.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

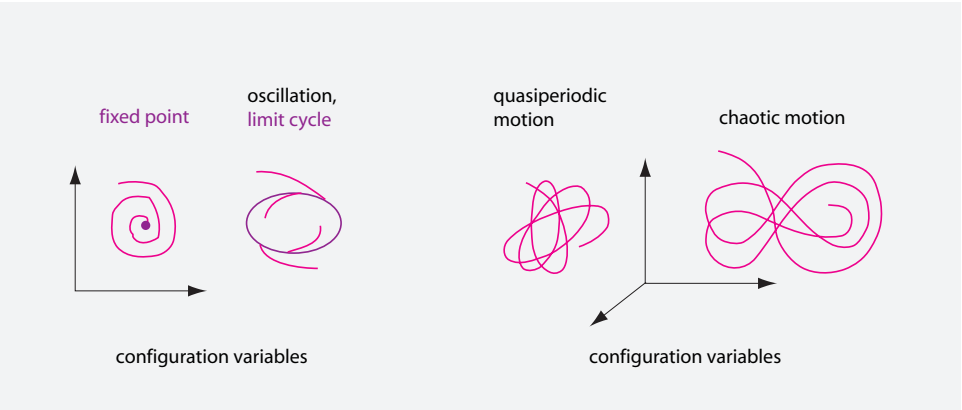

FIGURE 201 Examples of different types of motion in configuration space

such as the oscillation amplitude or the pattern amplitude. The first term λA is the driving term, in which λ is a parameter describing the strength of the driving. The next term is a typical nonlinearity in A, with μ a parameter that describes its strength, and the third term $\kappa \Delta A = \kappa(\partial^2 A/\partial x^2 + \partial^2 A/\partial y^2 + \partial^2 A/\partial z^2)$ is a typical diffusive and thus dissipative term.

One can distinguish two main situations. In cases where the dissipative term plays no role ($\kappa = 0$), one finds that when the driving parameter λ increases above zero, a *temporal* oscillation appears, i.e., a stable cycle with non-vanishing amplitude. In cases where the diffusive term does play a role, equation (105) describes how an amplitude for a *spatial* oscillation appears when the driving parameter λ becomes positive, as the solution $A = 0$ then becomes spatially unstable.

Challenge 588 ny

Challenge 589 ny

In both cases, the onset of order is called a *bifurcation*, because at this critical value of the driving parameter λ the situation with amplitude zero, i.e., the homogeneous (or unordered) state, becomes unstable, and the ordered state becomes stable. *In nonlinear systems, order is stable.* This is the main conceptual result of the field. Equation (105) and its numerous variations allow us to describe many phenomena, ranging from spirals, waves, hexagonal patterns, and topological defects, to some forms of turbulence. For every physical system under study, the main task is to distil the observable A and the parameters λ, μ and κ from the underlying physical processes.

Ref. 264

Self-organization is a vast field which is yielding new results almost by the week. To discover new topics of study, it is often sufficient to keep one's eye open; most effects are comprehensible without advanced mathematics. Good hunting!

Challenge 590 ny

Most systems that show self-organization also show another type of motion. When the driving parameter of a self-organizing system is increased to higher and higher values, order becomes more and more irregular, and in the end one usually finds chaos. For physicists, chaotic motion is the most irregular type of motion.* Chaos can be defined independently of self-organization, namely as that motion of systems for which

* On the topic of chaos, see the beautiful book by H.-O. Peitgen, H. Jürgens & D. Saupe, *Chaos and Fractals*, Springer Verlag, 1992. It includes stunning pictures, the necessary mathematical background, and some computer programs allowing personal exploration of the topic. 'Chaos' is an old word: according

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

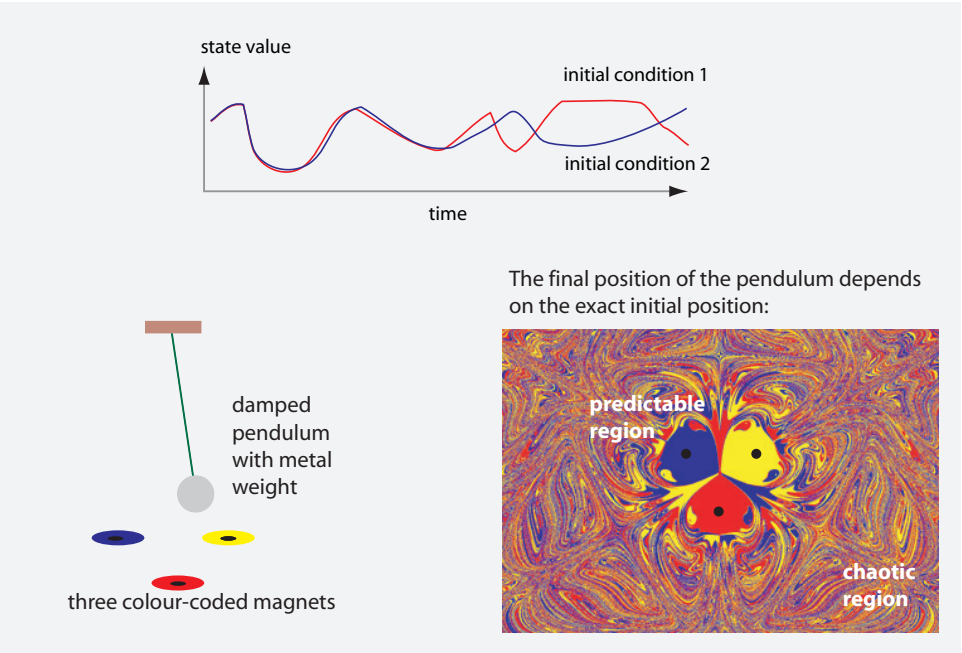

FIGURE 202 Chaos as sensitivity to initial conditions: the general case, and a simple chaotic system: a metal pendulum over three magnets (fractal © Paul Nylander)

small changes in initial conditions evolve into large changes of the motion (exponentially with time), as shown in Figure 202. More precisely, *chaos* is irregular motion characterized by a positive *Lyapounov exponent* in the presence of a strictly valid evolution.

A simple chaotic system is the damped pendulum above three magnets. Figure 202 shows how regions of predictability (around the three magnet positions) gradually change to region of unpredictability, for higher initial amplitudes. The weather is also a chaotic system, as are dripping water-taps, the fall of dice, and many other everyday systems. For example, research on the mechanisms by which the heart beat is generated has shown that the heart is not an oscillator, but a chaotic system with irregular cycles. This allows the heart to be continuously ready for demands for changes in beat rate which arise once the body needs to increase or decrease its efforts. Ref. 265

Incidentally, can you give a simple argument to show that the so-called *butterfly effect* does not exist? This 'effect' is often cited in newspapers. The claim is that nonlinearities imply that a small change in initial conditions can lead to large effects; thus a butterfly wing beat is alleged to be able to induce a tornado. Even though nonlinearities do indeed lead to growth of disturbances, the butterfly 'effect' has *never* been observed. Thus it does *not* exist. This 'effect' exists only to sell books and to get funding. Challenge 591 s

There is chaotic motion also in machines: chaos appears in the motion of trains on the rails, in gear mechanisms, and in fire-fighter's hoses. The precise study of the motion in a zippo cigarette lighter will probably also yield an example of chaos. The mathematical Challenge 592 ny

to Greek mythology, the first goddess, Gaia, i.e., the Earth, emerged from the chaos existing at the beginning.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

description of chaos – simple for some textbook examples, but extremely involved for others – remains an important topic of research.

All the steps from disorder to order, quasiperiodicity and finally to chaos, are examples of self-organization. These types of motion, illustrated in Figure 201, are observed in many fluid systems. Their study should lead, one day, to a deeper understanding of the mysteries of turbulence. Despite the fascination of this topic, we will not explore it further, because it does not lead towards the top of Motion Mountain.

Ref. 266

But self-organization is of interest also for a more general reason. It is sometimes said that our ability to formulate the patterns or rules of nature from observation does not imply the ability to predict *all* observations from these rules. According to this view, so-called 'emergent' properties exist, i.e., properties appearing in complex systems as something *new* that cannot be deduced from the properties of their parts and their interactions. (The ideological backdrop to this view is obvious; it is the last attempt to fight the determinism.) The study of self-organization has definitely settled this debate. The properties of water molecules do allow us to predict Niagara Falls.* Similarly, the diffusion of signal molecules do determine the development of a single cell into a full human being: in particular, cooperative phenomena determine the places where arms and legs are formed; they ensure the (approximate) right–left symmetry of human bodies, prevent mix-ups of connections when the cells in the retina are wired to the brain, and explain the fur patterns on zebras and leopards, to cite only a few examples. Similarly, the mechanisms at the origin of the heart beat and many other cycles have been deciphered.

Self-organization provides general principles which allow us in principle to predict the behaviour of complex systems of any kind. They are presently being applied to the most complex system in the known universe: the human brain. The details of how it learns to coordinate the motion of the body, and how it extracts information from the images in the eye, are being studied intensely. The ongoing work in this domain is fascinating. (A neglected case of self-organization is *humour*.) If you plan to become a scientist, consider taking this path.

Ref. 268

Challenge 594 ny

Self-organization research provided the final arguments that confirmed what J. Offrey de la Mettrie stated and explored in his famous book *L'homme machine* in 1748: humans are complex machines. Indeed, the lack of understanding of complex systems in the past was due mainly to the restrictive teaching of the subject of motion, which usually concentrated – as we do in this walk – on examples of motion in *simple* systems. The concepts of self-organization allow us to understand and to describe what happens during the functioning and the growth of organisms.

Even though the subject of self-organization provides fascinating insights, and will do so for many years to come, we now leave it. We continue with our own adventure, namely

---

She then gave birth to the other gods, the animals and the first humans.

* Already small versions of Niagara Falls, namely dripping water taps, show a large range of cooperative phenomena, including the chaotic, i.e., non-periodic, fall of water drops. This happens when the water flow has the correct value, as you can verify in your own kitchen. Several cooperative fluid phenomena have been simulated even on the molecular level.

FIGURE 206 The Belousov-Zhabotinski reaction: the liquid periodically changes colour, both in space and time. (© Yamaguchi University)

Challenge 598 ny wavy shape, as shown in Figure 204. Why?

* *

When water emerges from a oblong opening, the stream forms a braid pattern, as shown in Figure 205. This effect results from the interplay and competition between inertia and Ref. 269 surface tension: inertia tends to widen the stream, while surface tension tends to narrow it. Predicting the distance from one narrow region to the next is still a topic of research.

If the experiment is done in free air, without a plate, one usually observes an additional effect: there is a *chiral* braiding at the narrow regions, induced by the asymmetries of the water flow. You can observe this effect in the toilet! Scientific curiosity knows no limits: Challenge 599 e are you a right-turner or a left-turner, or both? On every day?

* *

A famous case of order appearance is the *Belousov-Zhabotinski reaction*. This mixture of chemicals spontaneously produces spatial and temporal patterns. Thin layers produce slowly rotating spiral patterns, as shown in Figure 206; Large, stirred volumes oscillate back and forth between two colours. A beautiful movie of the oscillations can be found on www.uni-r.de/Fakultaeten/nat_Fak_IV/Organische_Chemie/Didaktik/Keusch/D-oscill-d.htm. The exploration of this reaction led to the Nobel Prize in Chemistry for Ilya Prigogine in 1997.

* *

Gerhard Müller has discovered a simple but beautiful way to observe self-organization in solids. His system also provides a model for a famous geological process, the formation of hexagonal columns in basalt, such as the Giant's Causeway in Northern Ireland. Similar formations are found in many other places of the Earth. Just take some rice flour or Ref. 270 corn starch, mix it with about half the same amount of water, put the mixture into a Challenge 600 e pan and dry it with a lamp: hexagonal columns form. The analogy with basalt structures is possible because the drying of starch and the cooling of lava are diffusive processes governed by the same equations, because the boundary conditions are the same, and because both materials respond to cooling with a small reduction in volume.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

Water flow in pipes can be laminar (smooth) or turbulent (irregular and disordered). The transition depends on the diameter d of the pipe and the speed v of the water. The transition usually happens when the so-called *Reynolds number* – defined as $R = vd/\eta$ (η being the kinematic viscosity of the water, around $1\,mm^2/s$) – becomes greater than about 2000. However, careful experiments show that with proper handling, laminar flows can be produced up to $R = 100\,000$. A linear analysis of the equations of motion of the fluid, the Navier–Stokes equations, even predicts stability of laminar flow for *all* Reynolds numbers. This riddle was solved only in the years 2003 and 2004. First, a complex mathematical analysis showed that the laminar flow is not always stable, and that the transition to turbulence in a long pipe occurs with travelling waves. Then, in 2004, careful experiments showed that these travelling waves indeed appear when water is flowing through a pipe at large Reynolds numbers. Ref. 271

* *

For some beautiful pictures on self-organization in fluids, see the serve.me.nus.edu.sg/

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

limtt website. Among others, it shows that a circular vortex can 'suck in' a second one behind it, and that the process can then repeat.

* *

Also *dance* is an example of self-organization. Self-organization takes part in the brain. Like for all complex movements, learning them is often a challenge. Nowadays there are beautiful books that tell how physics can help you improve your dancing skills and the grace of your movements. Ref. 272

* *

Do you want to enjoy working on your PhD? Go into a scientific toy shop, and look for a toy that moves in a complex way. There are high chances that the motion is chaotic; explore the motion and present a thesis about it. For example, go to the extreme: explore the motion of a hanging rope whose upper end is externally driven. The system is fascinating.

* *

A famous example of self-organisation whose mechanisms are not well-known so far, is the *hiccup*. It is known that the vagus nerve plays a role in it. Like for many other examples of self-organisation, it takes quite some energy to get rid of a hiccup. Modern experimental research has shown that orgasms, which strongly stimulate the vagus nerve, are excellent ways to overcome hiccups. One of these researchers has won the 2006 IgNobel Prize for medicine for his work.

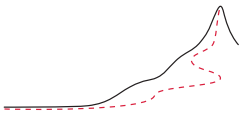
* *

Another important example of self-organisation is the *weather*. If you want to know more about the known connections between the weather and the quality of human life on Earth, free of any ideology, read the wonderful book by Reichholf. It explains how the weather between the continents is connected and describes how and why the weather changed in the last one thousand years. Ref. 273

Summary on self-organization and chaos

Appearance of order, in form of patterns, shapes and cycles, is not due to a decrease in entropy, but to a competition between driving causes and diffusive effects in open systems. Such appearance of order is predictable with (quite) simple equations. Chaos, the sensitivity to initial conditions, is common in strongly driven open systems, is at the basis of everyday chance, and often is described by simple equations. In nature, complexity is usually apparent: motion is simple.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 14

FROM THE LIMITATIONS OF PHYSICS TO THE LIMITS OF MOTION

> I only know that I know nothing.
> Socrates, as cited by Plato

Despite the general success of Galilean in engineering and in the description of everyday life, Socrates' saying still applies to Galilean physics. Let us see why.

Research topics in classical dynamics

Even though the science of mechanics is now several hundred years old, research into its details is still continuing.

We have already mentioned above the issue of the stability of the solar system. The long-term future of the planets is unknown. In general, the behaviour of few-body systems interacting through gravitation is still a research topic of mathematical physics. Answering the simple question of how long a given set of bodies gravitating around each other will stay together is a formidable challenge. The history of this so-called *many-body problem* is long and involved. Interesting progress has been achieved, but the final answer still eludes us.

Ref. 274

Many challenges remain in the fields of self-organization, of nonlinear evolution equations, and of chaotic motion; turbulence is the most famous example. These challenges motivate numerous researchers in mathematics, physics, chemistry, biology, medicine and the other sciences.

But apart from these research topics, classical physics leaves unanswered several basic questions.

What is contact?

> Democritus declared that there is a unique sort of motion: that ensuing from collision.
> Simplicius, *Commentary on the Physics of Aristotle*, 42, 10

Ref. 275

Of the questions unanswered by classical physics, the details of contact and collisions are among the most pressing. Indeed, we defined mass in terms of velocity changes during collisions. But why do objects change their motion in such instances? Why are collisions between two balls made of chewing gum different from those between two stainless-steel balls? What happens during those moments of contact?

Page 91

Contact is related to material properties, which in turn influence motion in a complex

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 46 Examples of errors in state-of-the art measurements (numbers in brackets give one standard deviation in the last digits), partly taken from physics.nist.gov/constants

Observation	Measurement	Precision / accuracy
Highest precision achieved: gyromagnetic ratio of the electron μ_e/μ_B	-1.001 159 652 181 11(74)	$7.4 \cdot 10^{-13}$
High precision: Rydberg constant	10 973 731.568 537(73) m^{-1}	$6.6 \cdot 10^{-12}$
High precision: astronomical unit	149 597 870.691(30) km	$2.0 \cdot 10^{-10}$
Industrial precision: part dimension tolerance in an automobile engine	1 µm of 20 cm	$5 \cdot 10^{-6}$
Low precision: gravitational constant G	$6.674\,28(67) \cdot 10^{-11}$ Nm^2/kg^2	$1.0 \cdot 10^{-4}$
Everyday precision: human circadian clock governing sleep	15 to 75 h	2

way. The complexity is such that the sciences of material properties developed independently from the rest of physics for a long time; for example, the techniques of metallurgy (often called the oldest science of all), of chemistry and of cooking were related to the properties of motion only in the twentieth century, after having been independently pursued for thousands of years. Since material properties determine the essence of contact, we *need* knowledge about matter and about materials to understand the notion of mass, and thus of motion. The parts of our mountain ascent that deal with quantum theory will reveal these connections.

Precision and accuracy

Challenge 601 e

Precision has its own fascination. How many digits of π, the ratio between circumference an diameter of a circle, do you know by heart? What is the largest number of digits of π you have calculated yourself?

When we started climbing Motion Mountain, we explained that gaining height means increasing the *precision* of our description of nature. To make even this statement itself more precise, we distinguish between two terms: *precision* is the degree of reproducibility; *accuracy* is the degree of correspondence to the actual situation. Both concepts apply to measurements,* to statements and to physical concepts.

Appendix C

At present, the record number of reliable digits ever measured for a physical quantity is between 12 and 13. Why so few? Classical physics doesn't provide an answer. What is the maximum number of digits we can expect in measurements; what determines it; and how can we achieve it? These questions are still open at this point in our ascent; they will be covered in the parts on quantum theory.

Challenge 602 s

On the other hand, statements with false accuracy abound. What should we think of a car company – Ford – who claim that the drag coefficient c_w of a certain model is 0.375? Or of the official claim that the world record in fuel consumption for cars is 2315.473 km/l? Or of the statement that 70.3 % of all citizens share a certain opinion?

* For measurements, both precision and accuracy are best described by their *standard deviation*, as explained in Appendix C, on page 920.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

One lesson we learn from investigations into measurement errors is that we should never provide more digits for a result than we can put our hand into fire for.

Challenge 603 s

Is it possible to draw or produce a rectangle for which the ratio of lengths is a real number, e.g. of the form 0.131520091514001315211420010914..., whose digits encode a book? (A simple method would code a space as 00, the letter 'a' as 01, 'b' as 02, 'c' as 03, etc. Even more interestingly, could the number be printed inside its own book?)

In our walk we aim for precision and accuracy, while avoiding false accuracy. Therefore, concepts have mainly to be *precise*, and descriptions have to be *accurate*. Any inaccuracy is a proof of lack of understanding. To put it bluntly, 'inaccurate' means *wrong*. Increasing the accuracy and precision of our description of nature implies leaving behind us all the mistakes we have made so far. That is our aim in the following.

Can all of nature be described in a book?

Let us have some fun with a puzzle related to our adventure. Could the perfect physics publication, one that describes all of nature, exist? If it does, it must also describe itself, its own production – including its readers and its author – and most important of all, its own contents. Is such a book possible? Using the concept of information, we can state that such a book should contain all information contained in the universe. Is this possible? Let us check the options.

If nature requires an *infinitely* long book to be fully described, such a publication obviously cannot exist. In this case, only approximate descriptions of nature are possible and a perfect physics book is impossible.

If nature requires a *finite* amount of information for its description, there are two options. One is that the information of the universe cannot be summarized in a book; then a perfect physics book is again impossible. The other option is that the universe does contain a finite amount of information and that it can be summarized in a few small statements. This would imply that the rest of the universe would not add to the information already contained in the perfect physics book. In this case, it seems that the entropy of the book and the entropy of the universe must be similar. This seems quite unlikely.

We note that the answer to this puzzle also implies the answer to another puzzle: whether a brain can contain a full description of nature. In other words, the real question is: can we understand nature? Is our hike to the top of motion mountain possible? We usually believe this. In short, we believe something which is rather unlikely: we believe that the universe does not contain more information than what our brain could contain or even contains already.

Page 1443
Challenge 604 e

Do we have an error in our arguments? Yes, we do. The terms 'universe' and 'information' are not used correctly in the above reasoning, as you might want to verify. We will solve this puzzle later in our adventure. Until then, do make up your own mind.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Something is wrong about our description of motion

> Darum kann es in der Logik auch *nie* Überraschungen geben.*
>
> Ludwig Wittgenstein, *Tractatus*, 6.1251

We described nature in a rather simple way. *Objects* are permanent and massive entities localized in space-time. *States* are changing properties of objects, described by position in space and instant in time, by energy and momentum, and by their rotational equivalents. *Time* is the relation between events measured by a clock. *Clocks* are devices in undisturbed motion whose position can be observed. *Space* and position is the relation between objects measured by a metre stick. *Metre sticks* are devices whose shape is subdivided by some marks, fixed in an invariant and observable manner. *Motion* is change of position with time (times mass); it is determined, does not show surprises, is conserved (even in death), and is due to gravitation and other interactions.

Even though this description works rather well, it contains a circular definition. Can you spot it? Each of the two central concepts of motion is defined with the help of the other. Physicists worked for about 200 years on classical mechanics without noticing or wanting to notice the situation. Even thinkers with an interest in discrediting science did not point it out. Can an exact science be based on a circular definition? Obviously, physics has done quite well so far. Some even say the situation is unavoidable in principle. Despite these opinions, undoing this logical loop is one of the aims of the rest of our walk. To achieve it, we need to increase substantially the level of precision in our description of motion.

Challenge 605 s

Challenge 606 s

Whenever precision is increased, imagination is restricted. We will discover that many types of motion that seem possible are not. Motion is limited. Nature limits speed, size, acceleration, mass, force, power and many other quantities. Continue reading the other parts of this adventure only if you are prepared to exchange fantasy for precision. It will be no loss, as you will gain something else: exploring the workings of nature will fascinate you even more.

Why is measurement possible?

In the description of gravity given so far, the one that everybody learns – or should learn – at school, acceleration is connected to mass and distance via $a = GM/r^2$. That's all. But this simplicity is deceiving. In order to check whether this description is correct, we have to measure lengths and times. However, it is *impossible* to measure lengths and time intervals with any clock or any ruler based on the gravitational interaction alone! Try to conceive such an apparatus and you will be inevitably be disappointed. You always need a non-gravitational method to start and stop the stopwatch. Similarly, when you measure length, e.g. of a table, you have to hold a ruler or some other device near it. The interaction necessary to line up the ruler and the table cannot be gravitational.

Challenge 607 s

A similar limitation applies even to mass measurements. Try to measure mass using gravitation alone. Any scale or balance needs other – usually mechanical, electromagnetic or optical – interactions to achieve its function. Can you confirm that the same applies to speed and to angle measurements? In summary, whatever method we use, *in*

Challenge 608 s

Challenge 609 s

* 'Hence there can *never* be surprises in logic.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

order to measure velocity, length, time, and mass, interactions other than gravity are needed. Our ability to measure shows that gravity is not all there is.

Page 317 In addition, we still have the open problem, mentioned above, that our measurement recipes define space and time measurements with help of objects and measurements on objects with help of space and time.

Galilean physics does not explain the ability to measure. In fact, it does not even explain the existence of standards. Why do objects have fixed lengths? Why do clocks work with regularity? Galilean physics cannot explain these observations.

Is motion unlimited?

Galilean physics suggests that motion could go on forever. In fact, Galilean physics makes no clear statements on the universe as a whole. It seems to suggest that it is infinite. Finitude does not fit with the Galilean description of motion. On the other hand, we know

Challenge 610 e that the universe is *not* infinite: if it were infinite, the night would not be dark. Galilean physics is thus limited in its explanations because it disregards the limits of motion.

Galilean physics also suggests that speeds can have any value. But the existence of infinite speeds in nature would not allow us to define time sequences. Clocks would be impossible. In other words, a description of nature that allows unlimited speeds is not precise. Precision requires limits. To achieve the highest possible precision, we need to discover all limits to motion. So far, we have discovered only one: there is a smallest entropy. We now turn to another, more striking one: the limit for speed. To understand this limit, we will explore the most rapid motion we know: the motion of light.

Appendix A

NOTATION AND CONVENTIONS

Newly introduced and defined concepts in this text are indicated by *italic typeface*. New definitions are also referred to in the index by italic page numbers. We naturally use SI units throughout the text; these are defined in Appendix C. Experimental results are cited with limited precision, usually only two digits, as this is almost always sufficient for our purposes. High-precision reference values can be found in Appendices C and E.

In relativity we use the time convention, where the metric has the signature $(+---)$. This is used in about 70 % of the literature worldwide. We use indices i, j, k for 3-vectors and indices a, b, c, etc. for 4-vectors. Other conventions specific to general relativity are explained as they arise in the text.

Ref. 276

The Latin alphabet

> What is written without effort is in general read without pleasure.
>
> Samuel Johnson

Ref. 277

Books are collections of symbols. *Writing* was probably invented between 3400 and 3300 BCE by the Sumerians in Mesopotamia (though other possibilities are also discussed). It then took over a thousand years before people started using symbols to represent sounds instead of concepts: this is the way in which the first alphabet was created. This happened between 2000 and 1600 BCE (possibly in Egypt) and led to the Semitic alphabet. The use of an alphabet had so many advantages that it was quickly adopted in all neighbouring cultures, though in different forms. As a result, the Semitic alphabet is the forefather of all alphabets used in the world.

This text is written using the Latin alphabet. At first sight, this seems to imply that its pronunciation *cannot* be explained in print, in contrast to the pronunciation of other alphabets or of the International Phonetic Alphabet (IPA). (They can be explained using the alphabet of the main text.) However, it *is* in principle possible to write a text that describes exactly how to move lips, mouth and tongue for each letter, using physical concepts where necessary. The descriptions of pronunciations found in dictionaries make indirect use of this method: they refer to the memory of pronounced words or sounds found in nature.

Historically, the Latin alphabet was derived from the Etruscan, which itself was a derivation of the Greek alphabet. There are two main forms.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The *ancient* Latin alphabet,
used from the sixth century BCE onwards:

A B C D E F Z H I K L M N O P Q R S T V X

The *classical* Latin alphabet,
used from the second century BCE until the eleventh century:

A B C D E F G H I K L M N O P Q R S T V X Y Z

The letter G was added in the third century BCE by the first Roman to run a fee-paying school, Spurius Carvilius Ruga. He added a horizontal bar to the letter C and substituted the letter Z, which was not used in Latin any more, for this new letter. In the second century BCE, after the conquest of Greece, the Romans included the letters Y and Z from the Greek alphabet at the end of their own (therefore effectively reintroducing the Z) in order to be able to write Greek words. This classical Latin alphabet was stable for the next thousand years.*

The classical Latin alphabet was spread around Europe, Africa and Asia by the Romans during their conquests; due to its simplicity it began to be used for writing in numerous other languages. Most modern 'Latin' alphabets include a few other letters. The letter W was introduced in the eleventh century in French and was then adopted in most European languages.** The letter U was introduced in the mid fifteenth century in Italy,
Ref. 278 the letter J at the end of that century in Spain, to distinguish certain sounds which had previously been represented by V and I. The distinction proved a success and was already common in most European languages in the sixteenth century. The contractions æ and œ date from the Middle Ages. Other Latin alphabets include more letters, such as the German *sharp s*, written ß, a contraction of 'ss' or 'sz', or the Nordic letters *thorn*, written
Ref. 279 Þ or þ, and *eth*, written Đ or ð, taken from the futhorc,*** and other signs.

Lower-case letters were not used in classical Latin; they date only from the Middle Ages, from the time of Charlemagne. Like most accents, such as ê, ç or ä, which were also first used in the Middle Ages, lower-case letters were introduced to save the then expensive paper surface by shortening written words.

> Outside a dog, a book is a man's best friend.
> Inside a dog, it's too dark to read.
>
> Groucho Marx

* To meet Latin speakers and writers, go to www.alcuinus.net.

** In Turkey, still in 2008, you can be convoked in front of a judge if you use the letters w, q or x in an official letter; these letters only exist in the Kurdish language, not in Turkish. Using them is 'unturkish' behaviour and punishable by law. It is not known to the author how physics teachers cope with this situation.

*** The Runic script, also called *Futhark* or *Futhorc*, a type of alphabet used in the Middle Ages in Germanic, Anglo–Saxon and Nordic countries, probably also derives from the Etruscan alphabet. The name derives from the first six letters: f, u, th, a (or o), r, k (or c). The third letter is the letter thorn mentioned above; it is often written 'Y' in Old English, as in 'Ye Olde Shoppe.' From the runic alphabet Old English also took the
Ref. 280 letter *wyn* to represent the 'w' sound, and the already mentioned eth. (The other letters used in Old English – not from futhorc – were the *yogh*, an ancient variant of g, and the ligatures æ or Æ, called *ash*, and œ or Œ, called *ethel*.)

TABLE 47 The ancient and classical Greek alphabets, and the correspondence with Latin and Indian digits

Anc.	Class.	Name	Corresp.		Anc.	Class.	Name	Corresp.	
A	A α	alpha	a	1	N	N ν	nu	n	50
B	B β	beta	b	2	Ξ	Ξ ξ	xi	x	60
Γ	Γ γ	gamma	g, n[1]	3	O	O o	omicron	o	70
Δ	Δ δ	delta	d	4	Π	Π π	pi	p	80
E	E ε	epsilon	e	5	Ϙ ϙ, ϟ		qoppa[3]	q	90
F ϝ, ς		digamma, stigma[2]	w	6	P	P ρ	rho	r, rh	100
					Σ	Σ σ, ς	sigma[4]	s	200
Z	Z ζ	zeta	z	7	T	T τ	tau	t	300
H	H η	eta	e	8		Υ υ	upsilon	y, u[5]	400
Θ	Θ θ	theta	th	9		Φ φ	phi	ph, f	500
I	I ι	iota	i, j	10		X χ	chi	ch	600
K	K κ	kappa	k	20		Ψ ψ	psi	ps	700
Λ	Λ λ	lambda	l	30		Ω ω	omega	o	800
M	M μ	mu	m	40	Ϡ ϡ		sampi[6]	s	900

The regional archaic letters yot, sha and san are not included in the table. The letter san was the ancestor of sampi.

1. Only if before velars, i.e., before kappa, gamma, xi and chi.
2. 'Digamma' is the name used for the F-shaped form. It was mainly used as a letter (but also sometimes, in its lower-case form, as a number), whereas the shape and name 'stigma' is used only for the number. Both names were derived from the respective shapes; in fact, the stigma is a medieval, uncial version of the digamma. The name 'stigma' is derived from the fact that the letter looks like a sigma with a tau attached under it – though unfortunately not in all modern fonts. The original letter name, also giving its pronunciation, was 'waw'.
3. The version of qoppa that looks like a reversed and rotated z is still in occasional use in modern Greek. Unicode calls this version 'koppa'.
4. The second variant of sigma is used only at the end of words.
5. Uspilon corresponds to 'u' only as the second letter in diphthongs.
6. In older times, the letter sampi was positioned between pi and qoppa.

The Greek alphabet

The Latin alphabet was derived from the Etruscan; the Etruscan from the Greek. The Greek alphabet was itself derived from the Phoenician or a similar northern Semitic alphabet in the tenth century BCE. The Greek alphabet, for the first time, included letters also for vowels, which the Semitic alphabets lacked (and often still lack). In the Phoenician alphabet and in many of its derivatives, such as the Greek alphabet, each letter has a proper name. This is in contrast to the Etruscan and Latin alphabets. The first two Greek letter names are, of course, the origin of the term *alphabet* itself.

Ref. 281

In the tenth century BCE, the Ionian or *ancient* (eastern) Greek alphabet consisted of the upper-case letters only. In the sixth century BCE several letters were dropped, while a few new ones and the lower-case versions were added, giving the *classical* Greek alphabet.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Still later, accents, subscripts and breathings were introduced. Table 47 also gives the values signified by the letters took when they were used as numbers. For this special use, the obsolete ancient letters were kept during the classical period; thus they also acquired lower-case forms.

The Latin correspondence in the table is the standard classical one, used for writing Greek words. The question of the correct *pronunciation* of Greek has been hotly debated in specialist circles; the traditional *Erasmian* pronunciation does not correspond either to the results of linguistic research, or to modern Greek. In classical Greek, the sound that sheep make was βη–βη. (Erasmian pronunciation wrongly insists on a narrow η; modern Greek pronunciation is different for β, which is now pronounced 'v', and for η, which is now pronounced as 'i:' – a long 'i'.) Obviously, the pronunciation of Greek varied from region to region and over time. For Attic Greek, the main dialect spoken in the classical period, the question is now settled. Linguistic research has shown that chi, phi and theta were less aspirated than usually pronounced in English and sounded more like the initial sounds of 'cat', 'perfect' and 'tin'; moreover, the zeta seems to have been pronounced more like 'zd' as in 'buzzed'. As for the vowels, contrary to tradition, epsilon is closed and short whereas eta is open and long; omicron is closed and short whereas omega is wide and long, and upsilon is really a 'u' sound as in 'boot', not like a French 'u' or German 'ü.'

The Greek vowels can have rough or smooth *breathings*, *subscripts*, and acute, grave, circumflex or diaeresis *accents*. Breathings – used also on ρ – determine whether the letter is aspirated. Accents, which were interpreted as stresses in the Erasmian pronunciation, actually represented pitches. Classical Greek could have up to three of these added signs per letter; modern Greek never has more than one.

Another descendant of the Greek alphabet* is the *Cyrillic alphabet*, which is used with slight variations, in many Slavic languages, such as Russian and Bulgarian. However, there is no standard transcription from Cyrillic to Latin, so that often the same Russian name is spelled differently in different countries or even in the same country on different occasions.

TABLE 48 The beginning of the Hebrew abjad

Letter	Name	Correspondence	
א	aleph	a	1
ב	beth	b	2
נ	gimel	g	3
ד	daleth	d	4
etc.			

* The Greek alphabet is also the origin of the *Gothic alphabet*, which was defined in the fourth century by Wulfila for the Gothic language, using also a few signs from the Latin and futhorc scripts.

The Gothic alphabet is not to be confused with the so-called *Gothic letters*, a style of the *Latin* alphabet used all over Europe from the eleventh century onwards. In Latin countries, Gothic letters were replaced in the sixteenth century by the *Antiqua*, the ancestor of the type in which this text is set. In other countries, Gothic letters remained in use for much longer. They were used in type and handwriting in Germany until 1941, when the National Socialist government suddenly abolished them, in order to comply with popular demand. They remain in sporadic use across Europe. In many physics and mathematics books, Gothic letters are used to denote vector quantities.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The Hebrew alphabet and other scripts

The phoenician alphabet is also the origin of the Hebrew consonant alphabet or *abjad*. Its first letters are given in Table 48. Only the letter aleph is commonly used in mathematics, though others have been proposed.

Ref. 282
Page 825

Around one hundred writing systems are in use throughout the world. Experts classify them into five groups. *Phonemic alphabets*, such as Latin or Greek, have a sign for each consonant and vowel. *Abjads* or consonant alphabets, such as Hebrew or Arabic, have a sign for each consonant (sometimes including some vowels, such as aleph), and do not write (most) vowels; most abjads are written from right to left. *Abugidas*, also called syllabic alphabets or alphasyllabaries, such as Balinese, Burmese, Devanagari, Tagalog, Thai, Tibetan or Lao, write consonants and vowels; each consonant has an inherent vowel which can be changed into the others by diacritics. *Syllabaries*, such as Hiragana or Ethiopic, have a sign for each syllable of the language. Finally, complex scripts, such as Chinese, Mayan or the Egyptian hieroglyphs, use signs which have both sound and meaning. Writing systems can have text flowing from right to left, from bottom to top, and can count book pages in the opposite sense to this book.

Even though there are about 7000 languages on Earth, there are only about one hundred writing systems used today. About fifty other writing systems have fallen out of use. * For physical and mathematical formulae, though, the sign system used in this text, based on Latin and Greek letters, written from left to right and from top to bottom, is a standard the world over. It is used independently of the writing system of the text containing it.

Ref. 283

Digits and numbers

Both the digits and the method used in this text to write numbers originated in India. They were brought to the Mediterranean by Arabic mathematicians in the Middle Ages. The number system used in this text is thus much younger than the alphabet.** The Indian numbers were made popular in Europe by Leonardo of Pisa, called Fibonacci,*** in his book *Liber Abaci* or 'Book of Calculation', which he published in 1202. That book revolutionized mathematics. Anybody with paper and a pen (the pencil had not yet been invented) was now able to calculate and write down numbers as large as reason allowed, or even larger, and to perform calculations with them. Fibonacci's book started:

> Novem figure indorum he sunt 9 8 7 6 5 4 3 2 1. Cum his itaque novem fig-

* A well-designed website on the topic is www.omniglot.com. The main present and past writing systems are encoded in the Unicode standard, which at present contains 52 writing systems. See www.unicode.org.

** The story of the development of the numbers is told most interestingly by G. Ifrah, *Histoire universelle des chiffres*, Seghers, 1981, which has been translated into several languages. He sums up the genealogy in ten beautiful tables, one for each digit, at the end of the book. However, the book contains many factual errors, as explained in the www.ams.org/notices/200201/rev-dauben.pdf and www.ams.org/notices/200202/rev-dauben.pdf review.

It is not correct to call the digits 0 to 9 *Arabic*. Both the actual Arabic digits and the digits used in Latin texts such as this one derive from the Indian digits. Only the digits 0, 2, 3 and 7 resemble those used in Arabic writing, and then only if they are turned clockwise by 90°.

*** Leonardo di Pisa, called Fibonacci (b. *c.* 1175 Pisa, d. 1250 Pisa), Italian mathematician, and the most important mathematician of his time.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

> uris, et cum hoc signo 0, quod arabice zephirum appellatur, scribitur quilibet numerus, ut inferius demonstratur.*

The Indian method of writing numbers consists of a large innovation, the *positional system*, and a small one, the digit zero. The positional system, as described by Fibonacci, was so much more efficient that it completely replaced the previous *Roman number system*, which writes 1996 as IVMM or MCMIVC or MCMXCVI, as well as the *Greek number system*, in which the Greek letters were used for numbers in the way shown in Table 47, thus writing 1996 as ,αϡϙς′. Compared to these systems, the Indian numbers are a much better technology. Indeed, the Indian system proved so practical that calculations done on paper completely eliminated the need for the *abacus*, which therefore fell into disuse. The abacus is still in use only in those countries which do not use a positional system to write numbers. (The Indian system also eliminated the need for systems to represent numbers with fingers. Such systems, which could show numbers up to 10 000 and more, have left only one trace: the term 'digit' itself, which derives from the Latin word for finger.) Similarly, only the positional number system allows mental calculations and made – and still makes – calculating prodigies possible.**

The symbols used in the text

> To avoide the tediouse repetition of these woordes: is equalle to: I will sette as I doe often in woorke use, a paire of paralleles, or Gemowe lines of one lengthe, thus: = , bicause noe .2. thynges, can be moare equalle.
>
> Robert Recorde***

Besides text and numbers, physics books contain other symbols. Most symbols have been developed over hundreds of years, so that only the clearest and simplest are now in use. In this mountain ascent, the symbols used as abbreviations for *physical* quantities are all taken from the Latin or Greek alphabets and are always defined in the context where they are used. The symbols designating units, constants and particles are defined in Appendices C and E. There is an international standard for them (ISO 31), but it is virtually inaccessible; the symbols used in this text are those in common use. Ref. 282

The *mathematical* symbols used in this text, in particular those for operations and relations, are given in the following list, together with their origins. The details of their history have been extensively studied in the literature. Ref. 285

* 'The nine figures of the Indians are: 9 8 7 6 5 4 3 2 1. With these nine figures, and with this sign 0 which in Arabic is called zephirum, any number can be written, as will be demonstrated below.'

** Currently, the shortest time for finding the thirteenth (integer) root of a hundred-digit number, a result with 8 digits, is 11.8 seconds. For more about the stories and the methods of calculating prodigies, see the bibliography. Ref. 284

*** Robert Recorde (*c.* 1510–1558), English mathematician and physician; he died in prison because of debts. The quotation is from his *The Whetstone of Witte*, 1557. An image showing the quote in manuscript can be found at the members.aol.com/jeff94100/witte.jpg website. It is usually suggested that the quote is the first introduction of the equal sign; claims that Italian mathematicians used the equal sign before Recorde are not backed up by convincing examples. Ref. 285

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Symbol	Meaning	Origin
$+, -$	plus, minus	J. Regiomontanus 1456; the plus sign is derived from Latin 'et'
$\sqrt{}$	read as 'square root'	used by C. Rudolff in 1525; the sign stems from a deformation of the letter 'r', initial of the Latin *radix*
$=$	equal to	R. Recorde 1557
$\{\}, [\,], (\,)$	grouping symbols	use starts in the sixteenth century
$>, <$	larger than, smaller than	T. Harriot 1631
$\times$	multiplied with, times	W. Oughtred 1631
$:$	divided by	G. Leibniz 1684
$\cdot$	multiplied with, times	G. Leibniz 1698
a^n	power	R. Descartes 1637
x, y, z	coordinates, unknowns	R. Descartes 1637
$ax+by+c=0$	constants and equations for unknowns	R. Descartes 1637
$\mathrm{d}/\mathrm{d}x$, $\mathrm{d}x$, $\int y\,\mathrm{d}x$	derivative, differential, integral	G. Leibniz 1675
φx	function of x	J. Bernoulli 1718
$fx, f(x)$	function of x	L. Euler 1734
$\Delta x, \sum$	difference, sum	L. Euler 1755
$\neq$	is different from	L. Euler eighteenth century
$\partial/\partial x$	partial derivative, read like 'd/dx'	it was derived from a cursive form of 'd' or of the letter 'dey' of the Cyrillic alphabet by A. Legendre in 1786
Δ	Laplace operator	R. Murphy 1833
$\lvert x\rvert$	absolute value	K. Weierstrass 1841
∇	read as 'nabla' (or 'del')	introduced by William Hamilton in 1853 and P.G. Tait in 1867, named after the shape of an old Egyptian musical instrument
$[x]$	the measurement unit of a quantity x	twentieth century
∞	infinity	J. Wallis 1655
π	$4\arctan 1$	H. Jones 1706
e	$\sum_{n=0}^{\infty}\frac{1}{n!} = \lim_{n\to\infty}(1+1/n)^n$	L. Euler 1736
i	$+\sqrt{-1}$	L. Euler 1777
$\cup, \cap$	set union and intersection	G. Peano 1888
$\in$	element of	G. Peano 1888
$\varnothing$	empty set	André Weil as member of the N. Bourbaki group in the early twentieth century
$\langle\psi\rvert, \lvert\psi\rangle$	bra and ket state vectors	Paul Dirac 1930
$\otimes$	dyadic product or tensor product or outer product	unknown

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Other signs used here have more complicated origins. The & sign is a contraction of Latin
Ref. 286 *et* meaning 'and', as is often more clearly visible in its variations, such as *&*, the common italic form.

Each of the punctuation signs used in sentences with modern Latin alphabets, such as , . ; : ! ? ‘ ’ » « – ( ) ... has its own history. Many are from ancient Greece, but the
Ref. 287 question mark is from the court of Charlemagne, and exclamation marks appear first in the sixteenth century.* The @ or *at-sign* probably stems from a medieval abbreviation
Ref. 288 of Latin *ad*, meaning 'at', similarly to how the & sign evolved from Latin *et*. In recent years, the *smiley* :-) and its variations have become popular. The smiley is in fact a new version of the 'point of irony' which had been formerly proposed, without success, by A. de Brahm (1868–1942).

The section sign § dates from the thirteenth century in northern Italy, as was shown
Ref. 289 by the German palaeographer Paul Lehmann. It was derived from ornamental versions of the capital letter C for *capitulum*, i.e., 'little head' or 'chapter.' The sign appeared first in legal texts, where it is still used today, and then spread into other domains.

The paragraph sign ¶ was derived from a simpler ancient form looking like the Greek letter Γ, a sign which was used in manuscripts from ancient Greece until well into the Middle Ages to mark the start of a new text paragraph. In the Middle Ages it took the modern form, probably because a letter c for *caput* was added in front of it.

Ref. 290 One of the most important signs of all, the *white space* separating words, was due to Celtic and Germanic influences when these people started using the Latin alphabet. It became commonplace between the ninth and the thirteenth century, depending on the language in question.

Calendars

The many ways to keep track of time differ greatly from civilization to civilization. The most common calendar, and the one used in this text, is also one of the most absurd, as it is a compromise between various political forces who tried to shape it.

In ancient times, independent localized entities, such as tribes or cities, preferred *lunar* calendars, because lunar timekeeping is easily organized locally. This led to the use of the month as a calendar unit. Centralized states imposed *solar* calendars, based on the year. Solar calendars require astronomers, and thus a central authority to finance them. For various reasons, farmers, politicians, tax collectors, astronomers, and some, but not all, religious groups wanted the calendar to follow the solar year as precisely as possible. The compromises necessary between days and years are the origin of leap days. The compromises necessary between months and year led to the varying lengths are different in different calendars. The most commonly used year–month structure was organized over 2000 years ago by Gaius Julius Ceasar, and is thus called the *Julian calendar*.

The system was destroyed only a few years later: August was lengthened to 31 days when it was named after Augustus. Originally, the month was only 30 days long; but in order to show that Augustus was as important as Caesar, after whom July is named, all month lengths in the second half of the year were changed, and February was shortened by an additional day.

Ref. 291 The *week* is an invention of Babylonia. One day in the Babylonian week was 'evil' or

* On the parenthesis see the beautiful book by J. Lennard, *But I Digress*, Oxford University Press, 1991.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

'unlucky', so it was better to do nothing on that day. The modern week cycle with its resting day descends from that superstition. (The way astrological superstition and astronomy cooperated to determine the order of the weekdays is explained in the section on gravitation.) Although about three thousand years old, the week was fully included into the Julian calendar only around the year 300, towards the end of the Western Roman Empire. The final change in the Julian calendar took place between 1582 and 1917 (depending on the country), when more precise measurements of the solar year were used to set a new method to determine leap days, a method still in use today. Together with a reset of the date and the fixation of the week rhythm, this standard is called the *Gregorian calendar* or simply the *modern calendar*. It is used by a majority of the world's population.

Page 174

Despite its complexity, the modern calendar does allow you to determine the day of the week of a given date in your head. Just execute the following six steps:

1. take the last two digits of the year, and divide by 4, discarding any fraction;
2. add the last two digits of the year;
3. subtract 1 for January or February of a leap year;
4. add 6 for 2000s or 1600s, 4 for 1700s or 2100s,
   2 for 1800s and 2200s, and 0 for 1900s or 1500s;
5. add the day of the month;
6. add the month key value, namely 144 025 036 146 for JFM AMJ JAS OND.

The remainder after division by 7 gives the day of the week, with the correspondence 1-2-3-4-5-6-0 meaning Sunday-Monday-Tuesday-Wednesday-Thursday-Friday-Saturday.*

When to start counting the years is a matter of choice. The oldest method not attached to political power structures was that used in ancient Greece, when years were counted from the first Olympic games. People used to say, for example, that they were born in the first year of the twenty-third Olympiad. Later, political powers always imposed the counting of years from some important event onwards.** Maybe reintroducing the Olympic

* Remembering the intermediate result for the current year can simplify things even more, especially since the dates 4.4, 6.6, 8.8, 10.10, 12.12, 9.5, 5.9, 7.11, 11.7 and the last day of February all fall on the same day of the week, namely on the year's intermediate result plus 4.

** The present counting of years was defined in the Middle Ages by setting the date for the foundation of Rome to the year 753 BCE, or 753 *before the Common Era*, and then counting backwards, so that the BCE years behave almost like negative numbers. However, the year 1 follows directly after the year 1 BCE: there was no year 0.

Some other standards set by the Roman Empire explain several abbreviations used in the text:
- *c.* is a Latin abbreviation for *circa* and means 'roughly';
- i.e. is a Latin abbreviation for *id est* and means 'that is';
- e.g. is a Latin abbreviation for *exempli gratia* and means 'for the sake of example';
- ibid. is a Latin abbreviation for *ibidem* and means 'at that same place';
- inf. is a Latin abbreviation for *infra* and means '(see) below';
- op. cit. is a Latin abbreviation for *opus citatum* and means 'the cited work';
- et al. is a Latin abbreviation for *et alii* and means 'and others'.

By the way, *idem* means 'the same' and *passim* means 'here and there' or 'throughout'. Many terms used in physics, like frequency, acceleration, velocity, mass, force, momentum, inertia, gravitation and temperature, are derived from Latin. In fact, it is arguable that the language of science has been Latin for over two thousand years. In Roman times it was Latin vocabulary with Latin grammar, in modern times it switched to Latin vocabulary with French grammar, then for a short time to Latin vocabulary with German grammar, after which it changed to Latin vocabulary with British/American grammar.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

counting is worth considering?

People Names

In the Far East, such as *Corea*, *Japan* or *China*, family names are put in front of the given name. For example, the first Japanese winner of the Nobel Prize in Physics was Yukawa Hideki. In *India*, often, but not always, there is no family name; in those cases, the father's first name is used. In *Russia*, the family name is never used, but the first name of the father. For example, Lev Landau was called Lev Davidovich ('son of David') in Russia. In addition, Russian translitteration is not standardized; it varies from country to country and from tradition to tradition. For example, one finds the spelling Tarski, Tarskii and Tarsky for the same person. In the *Netherlands*, the official given names are never used; every person has a semi-official first name by which he is called. For example, Gerard 't Hooft's official first name is Gerardus. In *Germany*, some family names have special pronounciations. For example, Voigt is pronounced 'Fohgt'. In *Italy*, during the Middle Age and the Renaissance, people were called by their first name only, such as Michelangelo or Galileo, or often by first name plus a personal surname that was not their family name, but was used like one, such as Niccolò Tartaglia or Leonardo Fibonacci. In *ancient Rome*, the name by which people are known is usually their surname. The family name was the middle name. For example, Cicero's family name was Tullius. The law introduced by Cicero was therefore known as 'lex Tullia'. In *ancient Greece*, there were no family names. People had only one name. In the English language, the Latin version of the name is used, such as Democritus.

Abbreviations and eponyms or concepts?

Sentences like the following are the scourge of modern physics:

> The EPR paradox in the Bohm formulation can perhaps be resolved using the GRW approach, using the WKB approximation of the Schrödinger equation.

Using such vocabulary is the best way to make language unintelligible to outsiders. First of all, it uses abbreviations, which is a shame. On top of this, the sentence uses people's names to characterize concepts, i.e., it uses *eponyms*. Originally, eponyms were intended as tributes to outstanding achievements. Today, when formulating radical new laws or variables has become nearly impossible, the spread of eponyms intelligible to a steadily decreasing number of people simply reflects an increasingly ineffective drive to fame.

Eponyms are a proof of scientist's lack of imagination. We avoid them as much as possible in our walk and give *common* names to mathematical equations or entities wherever possible. People's names are then used as appositions to these names. For example, 'Newton's equation of motion' is never called 'Newton's equation'; 'Einstein's field equations' is used instead of 'Einstein's equations'; and 'Heisenberg's equation of motion' is used instead of 'Heisenberg's equation'.

Ref. 292 Many units of measurement also date from Roman times, as explained in the next appendix. Even the infatuation with Greek technical terms, as shown in coinages such as 'gyroscope', 'entropy' or 'proton', dates from Roman times.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

However, some exceptions are inevitable: certain terms used in modern physics have no real alternatives. The Boltzmann constant, the Planck scale, the Compton wavelength, the Casimir effect, Lie groups and the Virasoro algebra are examples. In compensation, the text makes sure that you can look up the definitions of these concepts using the index. In addition, it tries to provide pleasurable reading.

BIBLIOGRAPHY

> Aiunt enim multum legendum esse, non multa.
> Plinius, *Epistulae*.*

1 For a history of science in antiquity, see Lucio Russo, *La rivoluzione dimenticata*, Feltrinelli 1996, also available in several other languages. Cited on page 22.

2 A beautiful book explaining physics and its many applications in nature and technology vividly and thoroughly is Paul G. Hewitt, John Suchocki & Leslie A. Hewitt, *Conceptual Physical Science*, Bejamin/Cummings, 1999.

A book famous for its passion for curiosity is Richard P. Feynman, Robert B. Leighton & Matthew Sands, *The Feynman Lectures on Physics*, Addison Wesley, 1977.

A lot can be learned about motion from quiz books. One of the best is the well-structured collection of beautiful problems that require no mathematics, written by Jean-Marc Lévy-Leblond, *La physique en questions – mécanique*, Vuibert, 1998.

Another excellent quiz collection is Yakov Perelman, *Oh, la physique*, Dunod, 2000, a translation from the Russian original.

A good problem book is W. G. Rees, *Physics by Example: 200 Problems and Solutions*, Cambridge University Press, 1994.

A good history of physical ideas is given in the excellent text by David Park, *The How and the Why*, Princeton University Press, 1988.

An excellent introduction into physics is Robert Pohl, *Pohl's Einführung in die Physik*, Klaus Lüders & Robert O. Pohl editors, Springer, 2004, in two volumes with CDs. It is a new edition of a book that is over 70 years old; but the didactic quality, in particular of the experimental side of physics, is unsurpassed.

Another excellent Russian physics problem book, the so-called *Saraeva*, seems to exist only as Portuguese translation: B.B. Bújovtsev, V.D. Krívchenkov, G.Ya. Miákishev & I.M. Saráeva *Problemas seleccionados de física elemental*, Mir, 1979.

Another good physics problem book is Giovanni Tonzig, *Cento errori di fisica pronti per l'uso*, Sansoni, third edition, 2006. See also his www.giovannitonzig.it website. Cited on pages 22, 107, 173, and 246.

3 An overview of motion illusions can be found on the excellent website www.michaelbach.de/ot. The complex motion illusion figure is found on www.michaelbach.de/ot/mot_rotsnake/index.html; it is a slight variation of the original by Kitaoka Akiyoshi at www.ritsumei.ac.jp/~akitaoka/rotsnake.gif, published as A. Kitaoka & H. Ashida,

* 'Read much, but not anything.' Ep. 7, 9, 15. Gaius Plinius Secundus (b. 23/4 Novum Comum, d. 79 Vesuvius eruption), Roman writer, especially famous for his large, mainly scientific work *Historia naturalis*, which has been translated and read for almost 2000 years.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Phenomenal characteristics of the peripheral drift illusion, *Vision* **15**, pp. 261–262, 2003. A famous scam is to pretend that the illusion is due to or depends on stress. Cited on page 23.

4 These and other fantastic illusions are also found in Akiyoshi Kitaoka, *Trick Eyes*, Barnes & Noble, 2005. Cited on page 23.

5 A well-known principle in the social sciences states that, given a question, for every possible answer, however weird it may seem, there is somebody – and often a whole group – who holds it as his opinion. One just has to go through literature (or the internet) to confirm this.

About group behaviour in general, see R. Axelrod, *The Evolution of Cooperation*, Harper Collins, 1984. The propagation and acceptance of ideas, such as those of physics, are also an example of human cooperation, with all its potential dangers and weaknesses. Cited on page 23.

6 All the known texts by Parmenides and Heraclitus can be found in Jean-Paul Dumont, *Les écoles présocratiques*, Folio-Gallimard, 1988. Views about the non-existence of motion have also been put forward by much more modern and much more contemptible authors, such as in 1710 by Berkeley. Cited on page 24.

Page 857

7 An example of people worried by Zeno is given by William McLaughlin, Resolving Zeno's paradoxes, *Scientific American* pp. 66–71, November 1994. The actual argument was not about a hand slapping a face, but about an arrow hitting the target. See also Ref. 53. Cited on page 24.

8 The full text of *La Beauté* and the other poems from *Les fleurs du mal*, one of the finest books of poetry ever written, can be found at the hypermedia.univ-paris8.fr/bibliotheque/Baudelaire/Spleen.html website. Cited on page 25.

9 The most famous text is Jearl Walker, *The Flying Circus of Physics*, Wiley, 1975. For more interesting physical effects in everyday life, see Erwein Flachsel, *Hundertfünfzig Physikrätsel*, Ernst Klett Verlag, 1985. The book also covers several clock puzzles, in puzzle numbers 126 to 128. Cited on page 25.

10 A concise and informative introduction into the history of classical physics is given in the first chapter of the book by F. K. Richtmeyer, E. H. Kennard & J. N. Cooper, *Introduction to Modern Physics*, McGraw–Hill, 1969. Cited on page 26.

11 An introduction into perception research is Bruce Goldstein, *Perception*, Books/Cole, 5th edition, 1998. Cited on pages 27 and 32.

12 A good overview over the arguments used to prove the existence of god from motion is given by Michael Buckley, *Motion and Motion's God*, Princeton University Press, 1971. The intensity of the battles waged around these failed attempts is one of the tragicomic chapters of history. Cited on page 27.

13 Thomas Aquinas, *Summa Theologiae* or *Summa Theologica*, 1265–1273, online in Latin at www.newadvent.org/summa, in English on several other servers. Cited on page 27.

14 For an exploration of 'inner' motions, see the beautiful text by Richard Schwartz, *Internal Family Systems Therapy*, The Guilford Press, 1995. Cited on page 27.

15 For an authoritative description of proper motion development in babies and about how it leads to a healthy character see Emmi Pikler, *Laßt mir Zeit - Die selbstständige Bewegungsentwicklung des Kindes bis zum freien Gehen*, Pflaum Verlag, 2001, and her other books. See also the website www.pikler.org. Cited on page 27.

16 See e.g. the fascinating text by David G. Chandler, *The Campaigns of Napoleon - The Mind and Method of History's Greatest Soldier*, Macmillan, 1966. Cited on page 27.

17 Richard Marcus, *American Roulette*, St Martin's Press, 2003, a thriller and a true story. Cited on page 27.

18 A good and funny book on behaviour change is the well-known text by R. Bandler, *Using Your Brain for a Change*, Real People Press, 1985. See also Richard Bandler & John Grinder, *Frogs into princes – Neuro Linguistic Programming*, Eden Grove Editions, 1990. Cited on pages 28 and 38.

19 A beautiful book about the mechanisms of human growth from the original cell to full size is Lewis Wolpert, *The Triumph of the Embryo*, Oxford University Press, 1991. Cited on page 28.

20 On the topic of grace and poise, see e.g. the numerous books on the Alexander technique, such as M. Gelb, *Body Learning – An Introduction to the Alexander Technique*, Aurum Press, 1981, and Richard Brennan, *Introduction to the Alexander Technique*, Little Brown and Company, 1996. Among others, the idea of the Alexander technique is to return to the situation that the muscle groups for sustention and those for motion are used only for their respective function, and not vice versa. Any unnecessary muscle tension, such as neck stiffness, is a waste of energy due to the use of sustention muscles for movement and of motion muscles for sustention. The technique teaches the way to return to the natural use of muscles.

Motion of animals was discussed extensively already in the seventeenth century by G. Borelli, *De motu animalium*, 1680. An example of a more modern approach is J. J. Collins & I. Stewart, Hexapodal gaits and coupled nonlinear oscillator models, *Biological Cybernetics* **68**, pp. 287–298, 1993. See also I. Stewart & M. Golubitsky, *Fearful Symmetry*, Blackwell, 1992. Cited on pages 29 and 108.

21 The results on the development of children mentioned here and in the following have been drawn mainly from the studies initiated by Jean Piaget; for more details on child development, see an upcoming chapter, on page 807. At www.piaget.org you can find the website maintained by the Jean Piaget Society. Cited on pages 30, 45, and 46.

22 The reptilian brain (eat? flee? ignore?), also called the R-complex, includes the brain stem, the cerebellum, the basal ganglia and the thalamus; the old mammalian (emotions) brain, also called the limbic system, contains the amygdala, the hypothalamus and the hippocampus; the human (and primate) (rational) brain, called the neocortex, consists of the famous grey matter. For images of the brain, see the atlas by John Nolte, *The Human Brain: An Introduction to its Functional Anatomy*, Mosby, fourth edition, 1999. Cited on page 31.

23 The lower left corner film can be reproduced on a computer after typing the following lines in the Mathematica software package: Cited on page 31.

```
    « Graphics'Animation'
Nxpixels=72; Nypixels=54; Nframes=Nxpixels 4/3;
Nxwind=Round[Nxpixels/4]; Nywind=Round[Nypixels/3];
front=Table[Round[Random[]],{y,1,Nypixels},{x,1,Nxpixels}];
back =Table[Round[Random[]],{y,1,Nypixels},{x,1,Nxpixels}];
frame=Table[front,{nf,1,Nframes}];
Do[ If[ x>n-Nxwind && x<n && y>Nywind && y<2Nywind,
  frame[[n,y,x]]=back[[y,x-n]] ],
     {x,1,Nxpixels}, {y,1,Nypixels}, {n,1,Nframes}];

  DisplayFunction-> Identity],   {nf,1,Nframes}]
ShowAnimation[film]
```

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

But our motion detection system is much more powerful than the example shown in the lower left corners. The following, different film makes the point.

```
    « Graphics'Animation'
Nxpixels=72; Nypixels=54; Nframes=Nxpixels 4/3;
Nxwind=Round[Nxpixels/4]; Nywind=Round[Nypixels/3];
front=Table[Round[Random[]],{y,1,Nypixels},{x,1,Nxpixels}];
back =Table[Round[Random[]],{y,1,Nypixels},{x,1,Nxpixels}];
frame=Table[front,{nf,1,Nframes}];
Do[ If[ x>n-Nxwind && x<n && y>Nywind && y<2Nywind,
  frame[[n,y,x]]=back[[y,x]] ],
     {x,1,Nxpixels}, {y,1,Nypixels}, {n,1,Nframes}];
film=Table[ListDensityPlot[frame[[nf]], Mesh-> False,
  Frame-> False, AspectRatio-> N[Nypixels/Nxpixels],
  DisplayFunction-> Identity],   {nf,1,Nframes}]
ShowAnimation[film]
```

Similar experiments, e.g. using randomly changing random patterns, show that the eye perceives motion even in cases where all Fourier components of the image are practically zero; such image motion is called *drift-balanced* or *non-Fourier* motion. Several examples are presented in J. Zanker, Modelling human motion perception I: Classical stimuli, *Naturwissenschaften* **81**, pp. 156–163, 1994, and J. Zanker, Modelling human motion perception II: Beyond Fourier motion stimuli, *Naturwissenschaften* **81**, pp. 200–209, 1994.

24 All fragments from Heraclitus are from John Mansley Robinson, *An Introduction to Early Greek Philosophy*, Houghton Muffin 1968, chapter 5. Cited on page 33.

25 An introduction to Newton the alchemist are the two books by Betty Jo Teeter Dobbs, *The Foundations of Newton's Alchemy*, Cambridge University Press, 1983, and *The Janus Face of Genius*, Cambridge University Press, 1992. Newton is found to be a sort of highly intellectual magician, desperately looking for examples of processes where gods interact with the material world. An intense but tragic tale. A good overview is provided by R. G. Keesing, Essay Review: Newton's Alchemy, *Contemporary Physics* **36**, pp. 117–119, 1995.

Newton's infantile theology, typical for god seekers who grew up without a father, can be found in the many books summarizing the letter exchanges between Clarke, his secretary, and Leibniz, Newton's rival for fame. Cited on page 39.

26 An introduction to the story of classical mechanics, which also destroys a few of the myths surrounding it – such as the idea that Newton could solve differential equations or that he introduced the expression $F = ma$ – is given by Clifford A. Truesdell, *Essays in the History of Mechanics*, Springer, 1968. Cited on pages 39, 152, and 179.

27 C. Liu, Z. Dutton, C. H. Behroozi & L. Vestergaard Hau, Observation of coherent optical information storage in an atomic medium using halted light pulses, *Nature* **409**, pp. 490–493, 2001. There is also a comment on the paper by E. A. Cornell, Stopping light in its track, **409**, pp. 461–462, 2001. However, despite the claim, the light pulses of course have *not* been halted. Can you give at least two reasons without even reading the paper, and maybe a third after reading it? Challenge 611 s

The work was an improvement on the previous experiment where a group velocity of light of 17 m/s had been achieved, in an ultracold gas of sodium atoms, at nanokelvin temperatures. This was reported by L. Vestergaard Hau, S. E. Harris, Z. Dutton & C. H. Behroozi, Light speed reduction to 17 meters per second in an ultracold atomic gas, *Nature* **397**, pp. 594–598, 1999. Cited on pages 41 and 634.

gencer **10**, pp. 21–28, 1998. Finally, there are the books by Bernard R. Gelbaum & John M. H. Olmsted, *counter-examples in Analysis*, Holden–Day, 1964, and their *Theorems and counter-examples in Mathematics*, Springer, 1993. Cited on page 60.

40 The beautiful but not easy text is Stan Wagon, *The Banach Tarski Paradox*, Cambridge University Press, 1993. Cited on pages 60 and 359.

41 About the shapes of salt water bacteria, see the corresponding section in the interesting book by Bernard Dixon, *Power Unseen – How Microbes Rule the World*, W.H. Freeman, 1994. The book has about 80 sections, in which as many microorganisms are vividly presented. Cited on page 61.

42 Olaf Medenbach & Harry Wilk, *Zauberwelt der Mineralien*, Sigloch Edition, 1977. It combines beautiful photographs with an introduction into the science of crystals, minerals and stones. About the largest crystals, see P. C. Rickwood, The largest crystals, **66**, pp. 885–908, 1981, also available on www.minsocam.org/MSA/collectors_corner/arc/large_crystals.htm. For an impressive example, the Naica cave in Mexico, see www.naica.com.mx/ingles/index.htm Cited on page 61.

43 The smallest distances are probed in particle accelerators; the distance can be determined from the energy of the particle beam. In 1996, the value of 10^{-19} m (for the upper limit of the size of quarks) was taken from the experiments described in F. Abe & al., Measurement of dijet angular distributions by the collider detector at Fermilab, *Physical Review Letters* 77, pp. 5336–5341, 1996. Cited on page 67.

44 These puzzles are taken from the puzzle collection at www.mathematische-basteleien.de. Cited on page 70.

45 Alexander K. Dewdney, *The Planiverse – Computer Contact with a Two-dimensional World*, Poseidon Books/Simon & Schuster, 1984. See also Edwin A. Abbott, *Flatland: A romance of many dimensions*, 1884. Several other fiction authors had explored the option of a two-dimensional universe before, always answering, incorrectly, in the affirmative. Cited on page 72.

46 On the world of fireworks, see the frequently asked questions list of the usenet group rec.pyrotechnics, or search the web. A simple introduction is the article by J. A. Conkling, Pyrotechnics, *Scientific American* pp. 66–73, July 1990. Cited on page 73.

47 There is a whole story behind the variations of g. It can be discovered in Chuji Tsuboi, *Gravity*, Allen & Unwin, 1979, or in Wolfgang Torge, *Gravimetry*, de Gruyter, 1989, or in Milan Burša & Karel Pěč, *The Gravity Field and the Dynamics of the Earth*, Springer, 1993. The variation of the height of the soil by up to 0.3 m due to the Moon is one of the interesting effects found by these investigations. Cited on pages 74 and 159.

48 Andrea Frova, *La fisica sotto il naso – 44 pezzi facili*, Biblioteca Universale Rizzoli, Milano, 2001. Cited on page 74.

49 On the other hands, other sciences enjoy studying usual paths in all detail. See, for example, Heini Hediger, editor, *Die Straßen der Tiere*, Vieweg & Sohn, 1967. Cited on page 75.

50 This was discussed in the *Frankfurter Allgemeine Zeitung*, 2nd of August, 1997, at the time of the world athletics championship. The values are for the fastest part of the race of a 100 m sprinter; the exact values cited were called the running speed world records in 1997, and were given as 12.048 m/s = 43.372 km/h by Ben Johnson for men, and 10.99 m/s = 39.56 km/h for women. Cited on page 75.

51 Long jump data and literature can be found in three articles all entitled Is a good long jumper a good high jumper?, in the *American Journal of Physics* **69**, pp. 104–105, 2001. In particular, world class long jumpers run at 9.35 ± 0.15 m/s, with vertical take-off speeds of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

3.35 ± 0.15 m/s, giving take-off angles of about (only) 20°. A new technique for achieving higher take-off angles would allow the world long jump record to increase dramatically. Cited on page 76.

52 The study of shooting faeces (i.e., shit) and its mechanisms is a part of modern biology. The reason that caterpillars do this was determined by M. Weiss, Good housekeeping: why do shelter-dwelling caterpillars fling their frass?, *Ecology Letters* **6**, pp. 361–370, 2003, who also gives the present record of 1.5 m for the 24 mg pellets of *Epargyreus clarus*. The picture of the flying frass is from S. Caveney, H. McLean & D. Surry, Faecal firing in a skipper caterpillar is pressure-driven, *The Journal of Experimental Biology* **201**, pp. 121–133, 1998. Cited on page 76.

53 The arguments of Zeno can be found in Aristotle, *Physics*, VI, 9. It can be found translated in almost any language. The classics.mit.edu/Aristotle/physics.6.vi.html website provides an online version in English. Cited on pages 80 and 331.

54 Etymology can be a fascinating topic, e.g. when research discovers the origin of the German word 'Weib' ('woman', related to English 'wife'). It was discovered, via a few texts in Tocharian – an extinct Indo-European language from a region inside modern China – to mean originally 'shame'. It was used for the female genital region in an expression meaning 'place of shame'. With time, this expression became to mean 'woman' in general, while being shortened to the second term only. This connection was discovered by the German linguist Klaus T. Schmidt; it explains in particular why the word is not feminine but neutral, i.e., why it uses the article 'das' instead of 'die'. Julia Simon, private communication.

Etymology can also be simple and plain fun, for example when one discovers in the *Oxford English Dictionary* that 'testimony' and 'testicle' have the same origin; indeed in Latin the same word 'testis' was used for both concepts. Cited on pages 83 and 92.

55 An overview of the latest developments is given by J. T. Armstrong, D. J. Hunter, K. J. Johnston & D. Mozurkewich, Stellar optical interferometry in the 1990s, *Physics Today* pp. 42–49, May 1995. More than 100 stellar diameters were known already in 1995. Several dedicated powerful instruments are being planned. Cited on page 83.

56 A good biology textbook on growth is Arthur F. Hopper & Nathan H. Hart, *Foundations of Animal Deveopment*, Oxford University Press, 2006. Cited on page 84.

57 This is discussed for example in C. L. Stong, The amateur scientist – how to supply electric power to something which is turning, *Scientific American* pp. 120–125, December 1975. It also discusses how to make a still picture of something rotating simply by using a few prisms, the so-called *Dove prisms*. Other examples of attaching something to a rotating body are given by E. Rieflin, Some mechanisms related to Dirac's strings, *American Journal of Physics* **47**, pp. 379–381, 1979. Cited on page 85.

58 James A. Young, Tumbleweed, *Scientific American* **264**, pp. 82–87, March 1991. The tumbleweed is in fact quite rare, except in in Hollywood westerns, where all directors feel obliged to give it a special appearance. Cited on page 85.

59 About N. decemspinosa, see R. L. Caldwell, A unique form of locomotion in a stomatopod – backward somersaulting, *Nature* **282**, pp. 71–73, 1979, and R. Full, K. Earls, M. Wong & R. Caldwell, Locomotion like a wheel?, *Nature* **365**, p. 495, 1993. About rolling caterpillars, see J. Brackenbury, Caterpillar kinematics, *Nature* **330**, p. 453, 1997, and J. Brackenbury, Fast locomotion in caterpillars, *Journal of Insect Physiology* **45**, pp. 525–533, 1999. More images around legs can be found on rjf9.biol.berkeley.edu/twiki/bin/view/PolyPEDAL/LabPhotographs. Cited on page 85.

60 The first experiments to prove the rotation of the flagella were by M. Silverman & M. I. Simon, Flagellar rotation and the mechanism of bacterial motility, *Nature* **249**,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

pp. 73–74, 1974. For some pretty pictures of the molecules involved, see K. Namba, A biological molecular machine: bacterial flagellar motor and filament, *Wear* **168**, pp. 189–193, 1993, or the website www.nanonet.go.jp/english/mailmag/2004/011a.html. The present record speed of rotation, 1700 rotations per second, is reported by Y. Magariyama, S. Sugiyama, K. Muramoto, Y. Maekawa, I. Kawagishi, Y. Imae & S. Kudo, Very fast flagellar rotation, *Nature* **371**, p. 752, 1994.

77 Serge Gracovetsky, *The Spinal Engine*, Springer Verlag, 1990. It is now also knon that human gait is chaotic. This is explained by M. Perc, The dynamics of human gait, *European Journal of Physics* **26**, pp. 525–534, 2005. Cited on page 109.

78 Duncan MacDougall, Hypothesis concerning soul substance together with experimental evidence of the existence of such substance, *American Medicine* **2**, pp. 240–243, April 1907, and Duncan MacDougall, Hypothesis concerning soul substance, *American Medicine* **2**, pp. 395–397, July 1907. Reading the papers shows that the author has little practice in performing reliable weight and time measurements. Cited on page 110.

79 A good roulette prediction story from the 1970s is told by Thomas A. Bass, *The Eudaemonic Pie* also published under the title *The Newtonian Casino*, Backinprint, 2000. An overview up to 1998 is given in the paper Edward O. Thorp, The invention of the first wearable computer, *Proceedings of the Second International Symposium on Wearable Computers* (ISWC 1998), 19-20 October 1998, Pittsburgh, Pennsylvania, USA (IEEE Computer Society), pp. 4–8, 1998, downloadable at csdl.computer.org/comp/proceedings/iswc/1998/9074/00/9074toc.htm. Cited on pages 111 and 1087.

80 This and many other physics surprises are described in the beautiful lecture script by Josef Zweck, *Physik im Alltag*, the notes of his lectures held in 1999/2000 at the Universität Regensburg. Cited on pages 111 and 136.

81 The equilibrium of ships, so important in car ferries, is an interesting part of shipbuilding; an introduction was already given by Leonhard Euler, Scientia navalis, 1749. Cited on page 112.

82 Thomas Heath, *Aristarchus of Samos – the Ancient Copernicus*, Dover, 1981, reprinted from the original 1913 edition. Aristarchos' treaty is given in Greek and English. Aristarchos was the first proposer of the heliocentric system. Aristarchos had measured the length of the day (in fact, by determining the number of days per year) to the astonishing precision of less than one second. This excellent book also gives an overview of Greek astronomy before Aristarchos, explained in detail for each Greek thinker. Aristarchos' text is also reprinted in Aristarchos, On the sizes and the distances of the Sun and the Moon, *c.* 280 BCE in Michael J. Crowe, *Theories of the World From Antiquity to the Copernican Revolution*, Dover, 1990, especially on pp. 27–29. Cited on page 116.

83 The influence of the Coriolis effect on icebergs was studied most thoroughly by the Swedish physicist turned oceanographer Walfrid Ekman (1874–1954); the topic was suggested by the great explorer Fridtjof Nansen, who also made the first observations. In his honour, one speaks of the Ekman layer, Ekman transport and Ekman spirals. Any text on oceanography or physical geography will give more details about them. Cited on page 118.

84 An overview of the effects of the Coriolis acceleration $\boldsymbol{a} = -2\boldsymbol{\omega} \times \boldsymbol{v}$ in the rotating frame is given by Edward A. Desloge, *Classical Mechanics*, Volume 1, John Wiley & Sons, 1982. Even the so-called *Gulf Stream*, the current of warm water flowing from the Caribbean to the North Sea, is influenced by it. Cited on page 118.

85 The original publication is by A. H. Shapiro, Bath-tub vortex, *Nature* **196**, pp. 1080–1081, 1962. He also produced two films of the experiment. The experiment has been repeated

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

many times in the northern and in the southern hemisphere, where the water drains clockwise; the first southern hemisphere test was L.M. Trefethen & al., The bath-tub vortex in the southern hemisphere, *Nature* **201**, pp. 1084–1085, 1965. A complete literature list is found in the letters to the editor of the *American Journal of Physics* **62**, p. 1063, 1994. Cited on page 118.

86 The tricks are explained by Richard Crane, Short Foucault pendulum: a way to eliminate the precession due to ellipticity, *American Journal of Physics* **49**, pp. 1004–1006, 1981, and particularly in Richard Crane, Foucault pendulum wall clock, *American Journal of Physics* **63**, pp. 33–39, 1993. The Foucault pendulum was also the topic of the thesis of Heike Kamerling Onnes, Nieuwe bewijzen der aswenteling der aarde, Universiteit Groningen, 1879. Cited on page 119.

87 The reference is J. G. Hagen, La rotation de la terre : ses preuves mécaniques anciennes et nouvelles, *Sp. Astr. Vaticana Second. App.* Rome, 1910. His other experiment is published as J. G. Hagen, How Atwood's machine shows the rotation of the Earth even quantitatively, International Congress of Mathematics, Aug. 1912. Cited on page 121.

88 The original papers are A. H. Compton, A laboratory method of demonstrating the Earth's rotation, *Science* **37**, pp. 803–806, 1913, A. H. Compton, Watching the Earth revolve, *Scientific American Supplement* no. 2047, pp. 196–197, 1915, and A. H. Compton, A determination of latitude, azimuth and the length of the day independent of astronomical observations, *Physical Review* (second series) **5**, pp. 109–117, 1915. Cited on page 121.

89 R. Anderson, H.R. Bilger & G.E. Stedman, The Sagnac-effect: a century of Earth-rotated interferometers, *American Journal of Physics* **62**, pp. 975–985, 1994.

See also the clear and extensive paper by G.E. Stedman, Ring laser tests of fundamental physics and geophysics, *Reports on Progress in Physics* **60**, pp. 615–688, 1997. Cited on page 121.

90 About the length of the day, see the maia.usno.navy.mil website, or the books by K. Lambeck, *The Earth's Variable Rotation: Geophysical Causes and Consequences*, Cambridge University Press, 1980, and by W. H. Munk & G. J. F. MacDonald, *The Rotation of the Earth*, Cambridge University Press, 1960. About a modern ring laser set-up, see www.wettzell.ifag.de. Cited on pages 122 and 160.

91 H. Bucka, Zwei einfache Vorlesungsversuche zum Nachweis der Erddrehung, *Zeitschrift für Physik* **126**, pp. 98–105, 1949, and H. Bucka, Zwei einfache Vorlesungsversuche zum Nachweis der Erddrehung. II. Teil, *Zeitschrift für Physik* **128**, pp. 104–107, 1950. Cited on page 122.

92 One example of data is by C. P. Sonett, E. P. Kvale, A. Zakharian, M. A. Chan & T. M. Demko, Late proterozoic and paleozoic tides, retreat of the moon, and rotation of the Earth, *Science* **273**, pp. 100–104, 5 July 1996. They deduce from tidal sediment analysis that days were only 18 to 19 hours long in the Proterozoic, i.e., 900 million years ago; they assume that the year was 31 million seconds long from then to today. See also C. P. Sonett & M. A. Chan, Neoproterozoic Earth-Moon dynamics – rework of the 900 MA Big Cottonwood canyon tidal laminae, *Geophysical Research Letters* **25**, pp. 539–542, 1998. Another determination was by G. E. Williams, Precambrian tidal and glacial clastic deposits: implications for precambrian Earth–Moon dynamics and palaeoclimate, *Sedimentary Geology* **120**, pp. 55–74, 1998. Using a geological formation called *tidal rhythmites*, he deduced that about 600 million years ago there were 13 months per year and a day had 22 hours. Cited on page 123.

93 The story of this combination of history and astronomy is told in Richard Stephenson, *Historical Eclispes and Earth's Rotation*, Cambridge University Press, 1996. Cited on

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

page 123.

94 On the rotation and history of the solar system, see S. Brush, Theories of the origin of the solar system 1956–1985, *Reviews of Modern Physics* **62**, pp. 43–112, 1990. Cited on page 123.

95 The website http://hpiers.obspm.fr/eop-pc shows the motion of the Earth's axis over the last ten years. The International Latitude Service founded by Küstner is now part of the International Earth Rotation Service; more information can be found on the www.iers.org website. The latest idea is that two-thirds of the circular component of the polar motion, which in the USA is called 'Chandler wobble' after the person who attributed to himself the discovery by Küstner, is due to fluctuations of the ocean pressure at the bottom of the oceans and one-third is due to pressure changes in the atmosphere of the Earth. This is explained by R. S. Gross, The excitation of the Chandler wobble, *Geophysical Physics Letters* **27**, pp. 2329–2332, 2000. Cited on page 125.

96 S. B. Lambert, C. Bizouard & V. Dehant, Rapid variations in polar motion during the 2005-2006 winter season, *Geophysical Research Letters* **33**, p. L13303, 2006. Cited on page 126.

97 For more information about Alfred Wegener, see the (simple) text by Klaus Rohrbach, *Alfred Wegener – Erforscher der wandernden Kontinente*, Verlag Freies Geistesleben, 1993; about plate tectonics, see the www.scotese.com website. About earthquakes, see the www.geo.ed.ac.uk/quakexe/quakes and the www.iris.edu/seismon website. See the vulcan.wr.usgs.gov and the www.dartmouth.edu/~volcano websites for information about volcanoes. Cited on page 126.

98 J. Jouzel & al., Orbital and millennial Antarctic climate variability over the past 800,000 years, *Science* **317**, pp. 793–796, 2007, takes the data from isotope concentrations in ice cores. In contrast, J. D. Hays, J. Imbrie & N. J. Shackleton, Variations in the Earth's orbit: pacemaker of the ice ages, *Science* **194**, pp. 1121–1132, 1976, confirmed the connection with orbital parameters by literally digging in the mud that covers the ocean floor in certain places. Note that the web is full of information on the ice ages. Just look up 'Milankovitch' in a search engine. Cited on page 130.

108 The material on the shadow discussion is from the book by Robert M. Pryce, *Cook and Peary*, Stackpole Books, 1997. See also the details of Peary's forgeries in Wally Herbert, *The Noose of Laurels*, Doubleday 1989. The sad story of Robert Peary is also told in the centenary number of *National Geographic*, September 1988. Since the National Geographic Society had financed Peary in his attempt and had supported him until the US Congress had declared him the first man at the Pole, the (partial) retraction is noteworthy. (The magazine then changed its mind again later on, to sell more copies, and now again claims that Peary reached the Noth Pole.) By the way, the photographs of Cook, who claimed to have been at the North Pole even before Peary, have the same problem with the shadow length. Both men have a history of cheating about their 'exploits'. As a result, the first man at the North Pole was probably Roald Amundsen, who arrived there a few years later, and who was also the first man at the South Pole. Cited on page 142.

109 The story is told in M. Nauenberg, Hooke, orbital motion, and Newton's Principia, *American Journal of Physics* **62**, 1994, pp. 331–350. Cited on page 143.

110 More details are given by D. Rawlins, in Doubling your sunsets or how anyone can measure the Earth's size with wristwatch and meter stick, *American Journal of Physics* **47**, 1979, pp. 126–128. Another simple measurement of the Earth radius, using only a sextant, is given by R. O'Keefe & B. Ghavimi-Alagha, in The World Trade Centre and the distance to the world's centre, *American Journal of Physics* **60**, pp. 183–185, 1992. Cited on page 144.

111 More details on astronomical distance measurements can be found in the beautiful little book by van Helden, *Measuring the Universe*, University of Chicago Press, 1985, and in Nigel Henbest & Heather Cooper, *The Guide to the Galaxy*, Cambridge University Press, 1994. Cited on page 144.

112 A lot of details can be found in M. Jammer, *Concepts of Mass in Classical and Modern Physics*, reprinted by Dover, 1997, and in *Concepts of Force, a Study in the Foundations of Mechanics*, Harvard University Press, 1957. These eclectic and thoroughly researched texts provide numerous details and explain various philosophical viewpoints, but lack clear statements and conclusions on the accurate description of nature; thus are not of help on fundamental issues.

Jean Buridan (*c.* 1295 to *c.* 1366) criticizes the distinction of sublunar and translunar motion in his book *De Caelo*, one of his numerous works. Cited on page 144.

204 A simple article explaining the tallness of trees is A. Mineyev, Trees worthy of Paul Bunyan, *Quantum* pp. 4–10, January–February 1994. (Paul Bunyan is a mythical giant lumberjack who is the hero of the early frontier pioneers in the United States.) Note that the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

transport of liquids in trees sets no limits on their height, since water is pumped up along tree stems (except in spring, when it is pumped up from the roots) by evaporation from the leaves. This works almost without limits because water columns, when nucleation is carefully avoided, can be put under tensile stresses of over 100 bar, corresponding to 1000 m. See also P. Nobel, *Plant Physiology*, Academic Press, 2nd Edition, 1999. Cited on page 255.

205 Such information can be taken from the excellent overview article by M. F. Ashby, On the engineering properties of materials, *Acta Metallurgica* **37**, pp. 1273–1293, 1989. The article explains the various general criteria which determine the selection of materials, and gives numerous tables to guide the selection. Cited on page 255.

206 The present record for negative pressure in water was achieved by Q. Zheng, D. J. Durben, G. H. Wolf & C. A. Angell, Liquids at large negative pressures: water at the homogeneous nucleation limit, *Science* **254**, pp. 829–832, 1991. Cited on page 257.

229 Thermostatics is difficult to learn also because it was not discovered in a systematic way. See C. Truesdell, *The Tragicomical History of Thermodynamics 1822–1854*, Springer Verlag, 1980. An excellent advanced textbook on thermostatics and thermodynamics is Linda Reichl, *A Modern Course in Statistical Physics*, Wiley, 2nd edition, 1998. Cited on page 278.

230 Gas expansion was the main method used for the definition of the official temperature scale. Only in 1990 were other methods introduced officially, such as total radiation thermometry

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

(in the range 140 K to 373 K), noise thermometry (2 K to 4 K and 900 K to 1235 K), acoustical thermometry (around 303 K), magnetic thermometry (0.5 K to 2.6 K) and optical radiation thermometry (above 730 K). Radiation thermometry is still the central method in the range from about 3 K to about 1000 K. This is explained in detail in R. L. Rusby, R. P. Hudson, M. Durieux, J. F. Schooley, P. P. M. Steur & C. A. Swenson, The basis of the ITS-90, *Metrologia* **28**, pp. 9–18, 1991. On the water boiling point see also page 953. Cited on page 278.

235 For an overview, see Christian Enss & Siegfried Hunklinger, *Low-Temperature Physics*, Springer, 2005. Cited on page 286.

236 The famous paper on Brownian motion which contributed so much to Einstein's fame is A. Einstein, Über die von der molekularkinetischen Theorie der Wärme geforderte Bewegung von in ruhenden Flüssigkeiten suspendierten Teilchen, *Annalen der Physik* **17**, pp. 549–560, 1905. In the following years, Einstein wrote a series of further papers elaborating on this topic. For example, he published his 1905 Ph.D. thesis as A. Einstein, Eine neue Bestimmung der Moleküldimensionen, *Annalen der Physik* **19**, pp. 289–306, 1906, and he corrected a small mistake in A. Einstein, Berichtigung zu meiner Arbeit: 'Eine neue Bestimmung der Moleküldimensionen', *Annalen der Physik* **34**, pp. 591–592, 1911, where, using new data, he found the value $6.6 \cdot 10^{23}$ for Avogadro's number. Cited on page 287.

237 The first tests of the prediction were performed by J. Perrin, *Comptes Rendus de l'Académie des Sciences* **147**, pp. 475–476, and pp. 530–532, 1908. He masterfully sums up the whole discussion in Jean Perrin, *Les atomes*, Librarie Félix Alcan, Paris, 1913. Cited on page 288.

238 Pierre Gaspard & al., Experimental evidence for microscopic chaos, *Nature* **394**, p. 865, 27 August 1998. Cited on page 288.

239 These points are made clearly and forcibly, as is his style, by van Kampen, Entropie, *Nederlands tijdschrift voor natuurkunde* **62**, pp. 395–396, 3 December 1996. Cited on page 290.

240 This is a disappointing result of all efforts so far, as Grégoire Nicolis always stresses in his university courses. Seth Lloyd has compiled a list of 31 proposed definitions of complexity,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

containing among others, fractal dimension, grammatical complexity, computational complexity, thermodynamic depth. See, for example, a short summary in *Scientific American* p. 77, June 1995. Cited on page 290.

241 Minimal entropy is discussed by L. Szilard, Über die Entropieverminderung in einem thermodynamischen System bei Eingriffen intelligenter Wesen, *Zeitschrift für Physik* **53**, pp. 840–856, 1929. This classic paper can also be found in English translation in his collected works. Cited on page 290.

CHALLENGE HINTS AND SOLUTIONS

> Never make a calculation before you know the answer.
>
> John Wheeler's motto

John Wheeler wanted people to estimate, to try and to guess; but not saying the guess out loud. A correct guess reinforces the physics instinct, whereas a wrong one leads to the pleasure of surprise. Guessing is thus an important first step in solving every problem.

Challenge 1, page 12: Do not hesitate to be demanding and strict. The next edition of the text will benefit from it.

Challenge 2, page 13: These topics are all addressed later in the text.

Challenge 3, page 23: There are many ways to distinguish real motion from an illusion of motion: for example, only real motion can be used to set something else into motion. In addition, the motion illusions of the figures show an important failure; nothing moves if the head and the paper remain fixed with respect to each other. In other words, the illusion only *amplifies* existing motion, it does not *create* motion from nothing.

Challenge 4, page 24: Without detailed and precise experiments, both sides can find examples to prove their point. Creation is supported by the appearance of mould or bacteria in a glass of water; creation is also supported by its opposite, namely traceless disappearance, such as the disappearance of motion. However, conservation is supported and creation falsified by all those investigations that explore assumed cases of appearance or disappearance in full detail.

Challenge 6, page 26: Political parties, sects, helping organizations and therapists of all kinds are typical for this behaviour.

Challenge 7, page 30: The issue is not yet completely settled for the motion of empty space, such as in the case of gravitational waves. In any case, empty space is not made of small particles of finite size, as this would contradict the transversality of gravity waves.

Challenge 8, page 32: The circular definition is: objects are defined as what moves with respect to the background, and the background is defined as what stays when objects change. We shall Page 317 return to this important issue several times in our adventure. It will require a certain amount of patience to solve it, though.

Challenge 9, page 34: Holes are not physical systems, because in general they cannot be tracked.

Challenge 10, page 34: See page 1097.

Challenge 11, page 36: Hint: yes, there is such a point.

Challenge 12, page 36: See Figure 208 for an intermediate step. A bubble bursts at a point, and then the rim of the hole increases rapidly, until it disappears on the antipodes. During that process the remaining of the bubble keeps its spherical shape, as shown in the figure. For a film of the

process, see www.youtube.com/watch?v=SpcXtmkk26Q. In other words, the final droplets that are ejected stem from the point of the bubble which is opposite to the point of puncture; they are never ejected from the centre of the bubble.

Challenge 13, page 36: A ghost can be a moving image; it cannot be a moving object, as objects cannot interpenetrate. See page 1068.

Challenge 14, page 36: If something could stop moving, motion could disappear into nothing. For a precise proof, one would have to show that no atom moves any more. So far, this has never been observed: motion is conserved. (Nothing in nature can disappear into nothing.)

Challenge 15, page 36: This would indeed mean that space is infinite; however, it is impossible to observe that something moves "for ever": nobody lives that long.

Challenge 16, page 36: How would you measure this?

Challenge 17, page 36: The number of reliable digits of a measurement result is a simple quantification of precision. More details can be found by looking up 'standard deviation' in the index.

Challenge 18, page 36: No; memory is needed for observation and measurements. This is the case for humans and measurement apparatus. Quantum theory will make this particularly clear.

Challenge 19, page 36: Note that you never have observed zero speed. There is always some measurement error which prevents one to say that something is zero. No exceptions!

Challenge 20, page 37: The necessary rope length is nh, where n is the number of wheels/pulleys.

Challenge 21, page 37: $(2^{64} - 1) = 18\,446\,744\,073\,700\,551\,615$ grains of wheat, with a grain weight of 40 mg, are 738 thousand million tons. Given a world harvest in 2006 of 606 million tons, the grains amount to about 1200 years of the world's wheat harvests.

The grain number calculation is simplified by using the formula $1 + m + m^2 + m^3 + ...m^n = (m^{n+1} - 1)/(m - 1)$, that gives the sum of the so-called *geometric sequence*. (The name is historical and is used as a contrast to the *arithmetic sequence* $1 + 2 + 3 + 4 + 5 + ...n = n(n + 1)/2$.) Can you prove the two expressions?

The chess legend is mentioned first by Abu-l 'Abbas Ahmand Ibn Khallikan (1211–1282)Khallikan, Ibn. King Shiram and king Balhait, also mentioned in the legend, are historical figures that lived between the second and fourth century CE. The legend appears to have combined two different stories. Indeed, the calculation of grains appears already in the year 947, in the famous text *Meadows of Gold and Mines of Precious Stones* by Abu ul-Hasan 'Ali ibn Husayn ibn 'Ali ul-Mas'udi.Masudi, Ibn

Challenge 22, page 37: In clean experiments, the flame leans inwards. But such experiments

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

are not easy, and sometimes the flame leans outwards. Just try it. Can you explain both observations?

Challenge 23, page 37: Accelerometers are the simplest motion detectors. They exist in form of piezoelectric devices that produce a signal whenever the box is accelerated and can cost as little as one euro. Another accelerometer that might have a future is an interference accelerometer that makes use of the motion of an interference grating; this device might be integrated in silicon. Other, more precise accelerometers use gyroscopes or laser beams running in circles.

Velocimeters and position detectors can also detect motion; they need a wheel or at least an optical way to look out of the box. Tachographs in cars are examples of velocimeters, computer mice are examples of position detectors.

A cheap enough device would be perfect to measure the speed of skiers or skaters. No such device exists yet.

Challenge 24, page 37: The ball rolls (or slides) towards the centre of the table, as the table centre is somewhat nearer to the centre of the Earth than the border; then the ball shoots over, performing an oscillation around the table centre. The period is 84 min, as shown in challenge 337. (This has never been observed, so far. Why?)

Challenge 25, page 37: Only if the acceleration never vanishes. Accelerations can be felt. Accelerometers are devices that measure accelerations and then deduce the position. They are used in aeroplanes when flying over the atlantic. If the box does not accelerate, it is impossible to say whether it moves or sits still. It is even impossible to say in which direction one moves. (Close your eyes in a train at night to confirm this.)

Challenge 26, page 37: The block moves twice as fast as the cylinders, independently of their radius.

Challenge 27, page 38: This methods is known to work with other fears as well.

Challenge 28, page 38: Three couples require 11 passages. Two couples require 5. For four or more couples there is no solution. What is the solution if there are n couples and $n-1$ places on the boat?

Challenge 29, page 38: Hint: there is an infinite number of such shapes. These curves are called also *Reuleaux curves*. Another hint: The 20 p and 50 p coins in the UK have such shapes. And yes, other shapes than cylinders are also possible: take a twisted square cylinder, for example.

Challenge 30, page 38: Conservation, relativity and minimization are valid generally. In some rare processes in nuclear physics, motion invariance is broke, as is mirror invariance. Continuity is known not to be valid at smallest length and time intervals, but not experiments has yet probed those domains, so that it is still valid in practice.

Challenge 31, page 39: In everyday life, this is correct; what happens when quantum effects are taken into account?

Challenge 32, page 41: Take the average distance change of two neighbouring atoms in a piece of quartz over the last million years. Do you know something still slower?

Challenge 33, page 40: There is only one way: compare the velocity to be measured with the speed of light. In fact, almost all physics textbooks, both for schools and for university, start with the definition of space and time. Otherwise excellent relativity textbooks have difficulties avoiding this habit, even those that introduce the now standard k-calculus (which is in fact the approach mentioned here). Starting with speed is the logically cleanest approach.

Challenge 34, page 42: There is no way to sense one's own motion if one is in vacuum. No way in principle. This result is often called the *principle of relativity*.

Page 132

In fact, there is a way to measure one's motion in space (though not in vacuum): measure your speed with respect to the background radiation. So one has to be careful about what is meant.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

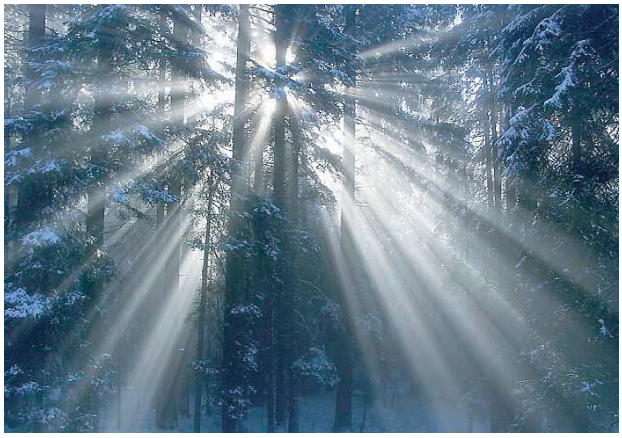

FIGURE 209 Sunbeams in a forest (© Fritz Bieri and Heinz Rieder)

Challenge 35, page 42: The wing load W/A, the ratio between weight W and wing area A, is obviously proportional to the third root of the weight. (Indeed, $W \sim l^3$, $A \sim l^2$, l being the dimension of the flying object.) This relation gives the green trend line.

The wing load W/A, the ratio between weight W and wing area A, is, like all forces in fluids, proportional to the square of the cruise speed v: we have $W/A = v^2 0.38\,\mathrm{kg/m^3}$. The unexplained factor contains the density of air and a general numerical coefficient that is difficult to calculate. This relation connects the upper and lower horizontal scales in the graph.

As a result, the cruise speed scales as the *sixth root* of weight: $v \sim W^{1/6}$. In other words, an Airbus A380 is 750 000 million times heavier than a fruit fly, but only a hundred times as fast.

Challenge 36, page 46: Equivalently: do points in space exist? The final part of our ascent studies this issue in detail; see page 1401.

Challenge 37, page 47: All electricity sources must use the same phase when they feed electric power into the net. Clocks of computers on the internet must be synchronized.

Challenge 38, page 47: Note that the shift increases quadratically with time, not linearly.

Challenge 39, page 47: Natural time is measured with natural motion. Natural motion is the motion of light. Natural time is thus defined with the motion of light.

Challenge 40, page 48: Galileo measured time with a scale (and with other methods). His stopwatch was a water tube that he kept closed with his thumb, pointing into a bucket. To start the stopwatch, he removed his thumb, to stop it, he put it back on. The volume of water in the bucket then gave him a measure of the time interval. This is told in his famous book Galileo Galilei, *Discorsi e dimostrazioni matematiche intorno a due nuove scienze attenenti alla mecanica e i movimenti locali*, usually simply called the 'Discorsi', which he published in 1638 with Louis Elsevier in Leiden, in the Netherlands.

Challenge 41, page 49: There is no way to define a local time at the poles that is consistent with all neighbouring points. (For curious people, check the website www.arctic.noaa.gov/gallery_np.html.)

Challenge 43, page 53: The forest is full of light and thus of light rays: they are straight, as shown by the sunbeams in Figure 209.

Challenge 44, page 53: One pair of muscles moves the lens along the third axis by deforming the eye from prolate to spherical to oblate.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 45, page 53: This you can solve trying to think in four dimensions. Try to imagine how to switch the sequence when two pieces cross. Note: it is usually *not* correct, in this domain, to use time instead of a fourth *spatial* dimension!

Challenge 46, page 55: Measure distances using light.

Challenge 49, page 58: It is easier to work with the unit torus. Take the unit interval $[0,1]$ and equate the end points. Define a set B in which the elements are a given real number b from the interval plus all those numbers who differ from that real by a rational number. The unit circle can be thought as the union of all the sets B. (In fact, every set B is a shifted copy of the rational numbers $\mathbb{Q}$.) Now build a set A by taking one element from each set B. Then build the set family consisting of the set A and its copies A_q shifted by a rational q. The union of all these sets is the unit torus. The set family is countably infinite. Then divide it into *two* countably infinite set families. It is easy to see that each of the two families can be renumbered and its elements shifted in such a way that each of the two families forms a unit torus.

Ref. 40 Mathematicians say that there is no countably infinitely additive measure of $\mathbb{R}^n$ or that sets such as A are non-measurable. As a result of their existence, the 'multiplication' of lengths is possible. Later on we shall explore whether bread or *gold* can be multiplied in this way.

Challenge 50, page 59: Hint: start with triangles.

Challenge 51, page 59: An example is the region between the x-axis and the function which assigns 1 to every transcendental and 0 to every non-transcendental number.

Challenge 52, page 60: We use the definition of the function of the text. The dihedral angle of a regular tetrahedron is an irrational multiple of π, so the tetrahedron has a non-vanishing Dehn invariant. The cube has a dihedral angle of $\pi/2$, so the Dehn invariant of the cube is 0. Therefore, the cube is not equidecomposable with the regular tetrahedron.

Challenge 53, page 60: If you think you can show that empty space is continuous, you are wrong. Check your arguments. If you think you can prove the opposite, you *might* be right – but only if you already know what is explained in the final part of the text. If that is not the case, check your arguments.

Challenge 54, page 61: Obviously, we use light to check that the plumb line is straight, so the two definitions must be the same. This is the case because the field lines of gravity are also possible paths for the motion of light. However, this is not always the case; can you spot the exceptions?

Another way to check straightness is along the surface of calm water.

A third, less precise way, way is to make use of the straightness sensors on the brain. The human brain has a built-in faculty to determine whether an objects seen with the eyes is straight. There are special cells in the brain that fore when this is the case. Any book on vision perception tells more about this topic.

Challenge 55, page 61: The hollow Earth theory is correct if the distance formula is used consistently. In particular, one has to make the assumption that objects get smaller as they approach the centre of the hollow sphere. Good explanations of all events are found on www.geocities.com/inversedearth. Quite some material can be found on the internet, also under the names of celestrocentric system, inner world theory or concave Earth theory. There is no way to prefer one description over the other, except possibly for reasons of simplicity or intellectual laziness.

Challenge 57, page 62: A hint is given in Figure 210. For the measurement of the speed of light with almost the same method, see page 404.

Challenge 58, page 62: A fast motorbike is faster: a driver can catch an arrow, a stunt that was shown on a television show.

Challenge 59, page 62: See Figure 212.

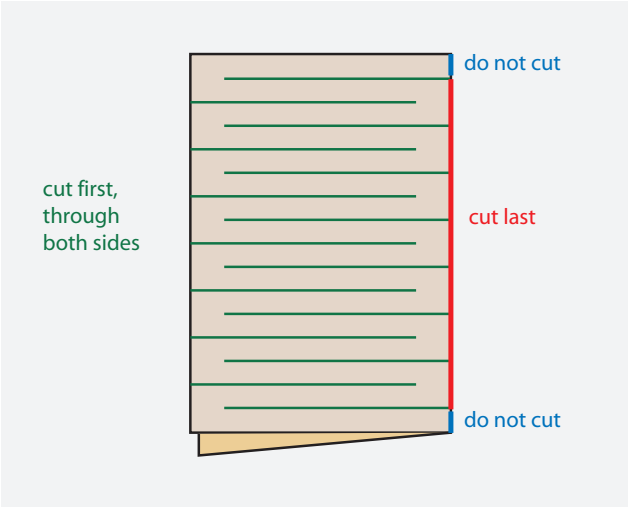

FIGURE 212 How to make a hole in a postcard that allows stepping through it

Challenge 60, page 63: Within 1 per cent, one *fifth* of the height must be empty, and four fifths must be filled; the exact value follows from $\sqrt[3]{2} = 1.25992...$

Challenge 61, page 64: The bear is white, because the obvious spot of the house is at the North pole. But there are infinitely many additional spots (without bears) near the South pole: can you find them?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 62, page 64: We call L the initial length of the rubber band, v the speed of the snail relative to the band and V the speed of the horse relative to the floor. The speed of the snail relative to the floor is given as

$$\frac{\mathrm{d}s}{\mathrm{d}t} = v + V\frac{s}{L+Vt} \,. \tag{106}$$

This is a so-called *differential equation* for the unknown snail position $s(t)$. You can check – by simple insertion – that its solution is given by

$$s(t) = \frac{v}{V}(L+Vt)\ln(1+Vt/L) \,. \tag{107}$$

Therefore, the snail reaches the horse at a time

$$t_{\text{reaching}} = \frac{L}{V}(e^{V/v}-1) \tag{108}$$

which is finite for all values of L, V and v. You can check however, that the time is very large indeed, if realistic speed values are used.

Challenge 63, page 64: Colour is a property that applies only to objects, not to boundaries. The question shows that it is easy to ask questions that make no sense also in physics.

Challenge 64, page 64: You can do this easily yourself. You can even find websites on the topic.

Challenge 66, page 64: Clocks with two hands: 22 times. Clocks with three hands: 2 times.

Challenge 67, page 65: For two hands, the answer is 143 times.

Challenge 68, page 65: The Earth rotates with 15 minutes per minute.

Challenge 69, page 65: You might be astonished, but no reliable data exist on this question. The highest speed of a throw measured so far seems to be a 45 m/s cricket bowl. By the way, much more data are available for speeds achieved with the help of rackets. The *c.* 70 m/s of fast badminton smashes seem to be a good candidate for record racket speed; similar speeds are achieved by golf balls.

Challenge 70, page 65: Yes, it can. In fact, many cats can slip through as well.

Challenge 71, page 65: 1.8 km/h or 0.5 m/s.

Challenge 73, page 65: The different usage reflects the idea that we are able to determine our position by ourselves, but not the time in which we are. The section on determinism will show Page 186 how wrong this distinction is.

Challenge 74, page 65: Yes, there is. However, this is not obvious, as it implies that space and time are not continuous, in contrast to what we learn in primary school. The answer will be found in the final part of this text.

Challenge 75, page 65: For a curve, use, at each point, the curvature radius of the circle approximating the curve in that point; for a surface, define two directions in each point and use two such circles along these directions.

Challenge 76, page 65: It moves about 1 cm in 50 ms.

Challenge 77, page 65: The surface area of the lung is between 100 and 200 m^2, depending on the literature source, and that of the intestines is between 200 and 400 m^2.

Challenge 78, page 66: A limit does not exist in classical physics; however, there is one in nature which appears as soon as quantum effects are taken into account.

Challenge 79, page 66: The final shape is a full cube without any hole.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

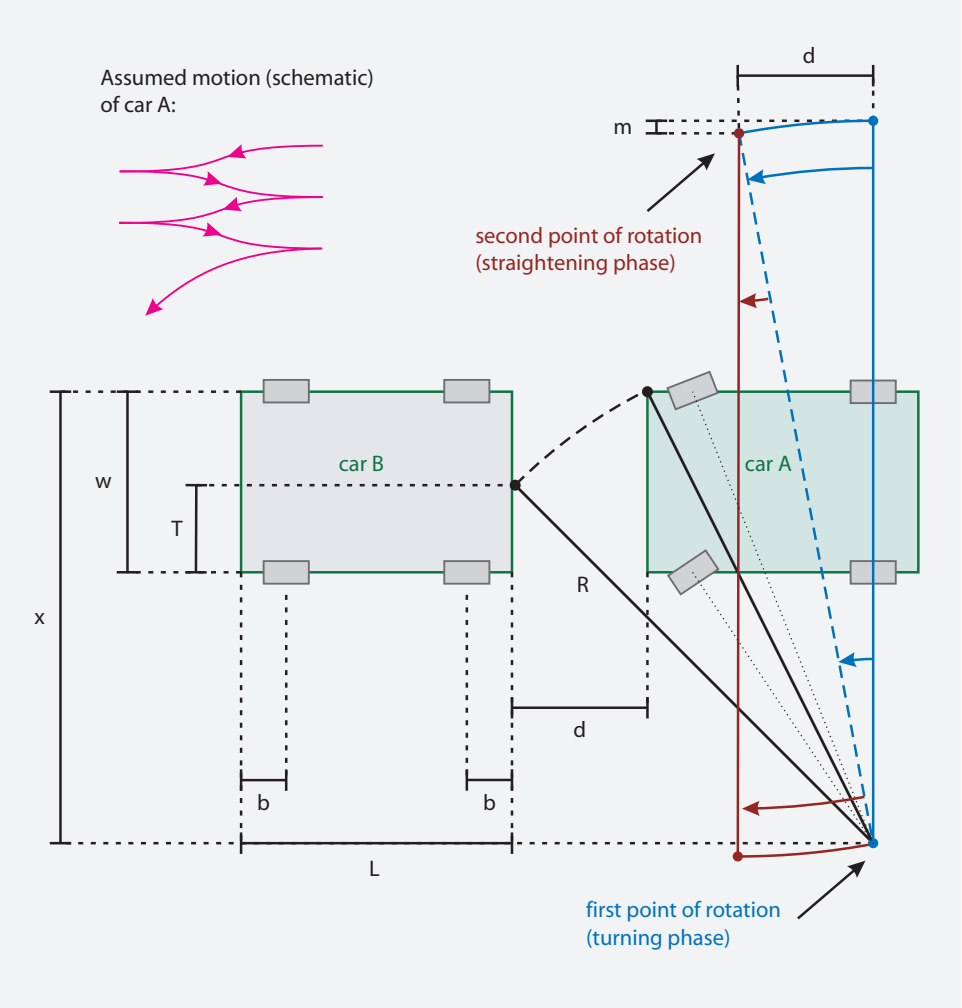

FIGURE 213 Solving the car parking puzzle (© Daniel Hawkins)

Challenge 80, page 66: The required gap is

$$= \sqrt{(L-b)^2 - w^2 + 2w\sqrt{R^2 - (L-b)^2}} - L + b \,, \tag{109}$$

as deduced from Figure 211.

Challenge 81, page 66: A smallest gap does not exist: any value will do! Can you show this?

Challenge 82, page 66: The following solution was proposed by Daniel Hawkins.

Assume you are sitting in car A, parked behind car B, as shown in Figure 213. There are two basic methods for exiting a parking space that requires the reverse gear: rotating the car to move the centre of rotation away from (to the right of) car B, and shifting the car downward to move the centre of rotation away from (farther below) car B. The first method requires car A to be partially diagonal, which means that the method will not work for d less than a certain value, essentially

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the value given above, when no reverse gear is needed. We will concern ourselves with the second method (pictured), which will work for an infinitesimal d.

In the case where the distance d is less than the minimum required distance to turn out of the parking space without using the reverse gear for a given geometry L, w, b, R, an attempt to turn out of the parking space will result in the corner of car A touching car B at a distance T away from the edge of car B, as shown in Figure 213. This distance T is the amount by which car A must be translated downward in order to successfully turn out of the parking space.

The method to leave the parking space, shown in the top left corner of Figure 213, requires two phases to be successful: the initial **turning phase**, and the **straightening phase**. By turning and straightening out, we achieve a vertical shift downward and a horizontal shift left, while preserving the original orientation. That last part is key because if we attempted to turn until the corner of car A touched car B, car A would be rotated, and any attempt to straighten out would just follow the same arc backward to the initial position, while turning the wheel the other direction would rotate the car even more, as in the first method described above.

Our goal is to turn as far as we can and still be able to completely straighten out by time car A touches car B. To analyse just how much this turn should be, we must first look at the properties of a turning car.

Ackermann steering is the principle that in order for a car to turn smoothly, all four wheels must rotate about the same point. This was patented by Rudolph Ackermann in 1817. Some properties of Ackermann steering in relation to this problem are as follows:

- The back wheels stay in alignment, but the front wheels (which we control), must turn different amounts to rotate about the same centre.
- The centres of rotation for left and right turns are on opposite sides of the car
- For equal magnitudes of left and right turns, the centres of rotation are equidistant from the nearest edge of the car. Figure 213 makes this much clearer.
- All possible centres of rotation are on the same line, which also always passes through the back wheels.
- When the back wheels are "straight" (straight will always mean in the same orientation as the initial position), they will be vertically aligned with the centres of rotation.
- When the car is turning about one centre, say the one associated with the maximum left turn, then the potential centre associated with the maximum right turn will rotate along with the car. Similarly, when the cars turns about the right centre, the left centre rotates.

Now that we know the properties of Ackermann steering, we can say that in order to maximize the shift downward while preserving the orientation, we must turn left about the 1st centre such that the 2nd centre rotates a *horizontal* distance d, as shown in Figure 213. When this is achieved, we brake, and turn the steering wheel the complete opposite direction so that we are now turning right about the 2nd centre. Because we shifted leftward d, we will straighten out at the exact moment car A comes in contact with car B. This results in our goal, a downward shift m and leftward shift d while preserving the orientation of car A. A similar process can be performed in reverse to achieve another downward shift m and a *rightward* shift d, effectively moving car A from its initial position (before any movement) downward $2m$ while preserving its orientation. This can be done indefinitely, which is why it is possible to get out of a parking space with an infinitesimal d between car A and car B. To determine how many times this procedure (both sets of turning and straightening) must be performed, we must only divide T (remember T is the amount by which car A must be shifted downward in order to turn out of the parking spot

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

normally) by $2m$, the total downward shift for one iteration of the procedure. Symbolically,

$$n = \frac{T}{2m}$$

In order to get an expression for n in terms of the geometry of the car, we must solve for T and $2m$. To simplify the derivations we define a new length x, also shown in Figure 213.

$$x = \sqrt{R^2 - (L-b)^2}$$

$$\begin{aligned} T + (x - w) &= \sqrt{R^2 - (L-b+d)^2} \\ T &= \sqrt{R^2 - (L-b+d)^2} - x + w \\ &= \sqrt{R^2 - (L-b+d)^2} - \sqrt{R^2 - (L-b)^2} + w \end{aligned}$$

$$\begin{aligned} (x + (x-w)) - m &= \sqrt{(x + (x-w))^2 - d^2} \\ m &= 2x - w - \sqrt{(2x-w)^2 - d^2} \\ &= 2\sqrt{R^2 - (L-b)^2} - w - \sqrt{(2\sqrt{R^2 - (L-b)^2} - w)^2 - d^2} \\ &= 2\sqrt{R^2 - (L-b)^2} - w - \sqrt{4(R^2 - (L-b)^2) - 4w\sqrt{R^2 - (L-b)^2} + w^2 - d^2} \\ &= 2\sqrt{R^2 - (L-b)^2} - w - \sqrt{4R^2 - 4(L-b)^2 - 4w\sqrt{R^2 - (L-b)^2} + w^2 - d^2} \\ 2m &= 4\sqrt{R^2 - (L-b)^2} - 2w - 2\sqrt{4R^2 - 4(L-b)^2 - 4w\sqrt{R^2 - (L-b)^2} + w^2 - d^2} \end{aligned}$$

$$\begin{aligned} n &= \frac{T}{2m} \\ &= \frac{\sqrt{R^2 - (L-b+d)^2} - \sqrt{R^2 - (L-b)^2} + w}{4\sqrt{R^2 - (L-b)^2} - 2w - 2\sqrt{4R^2 - 4(L-b)^2 - 4w\sqrt{R^2 - (L-b)^2} + w^2 - d^2}} \end{aligned}$$

The value of n must always be rounded *up* to the next integer to determine how many times one must go backward and forward to leave the parking spot.

Challenge 83, page 67: Nothing, neither a proof nor a disproof.

Challenge 84, page 67: See page 405. On shutters, see also the discussion on page 1492.

Challenge 85, page 67: A hint for the solution is given by Figure 214.

Challenge 86, page 67: Because they are or were liquid.

Challenge 87, page 67: The shape is shown in Figure 215; it has eleven lobes.

Challenge 88, page 68: The cone angle φ, the angle between the cone axis and the cone border (or equivalently, *half* the apex angle of the cone) is related to the solid angle Ω through the relation $\Omega = 2\pi(1 - \cos\varphi)$. Use the surface area of a spherical cap to confirm this result.

Challenge 90, page 68: See Figure 216.

Challenge 93, page 69: Hint: draw all objects involved.

Challenge 94, page 69: The curve is obviously called a *catenary*, from Latin 'catena' for chain. The formula for a catenary is $y = a\cosh(x/a)$. If you approximate the chain by short straight

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

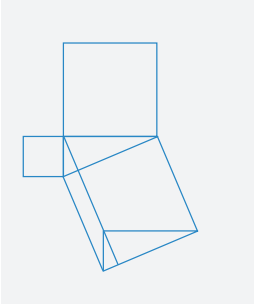

FIGURE 214 A simple drawing – one of the many possible one – proving Pythagoras' theorem

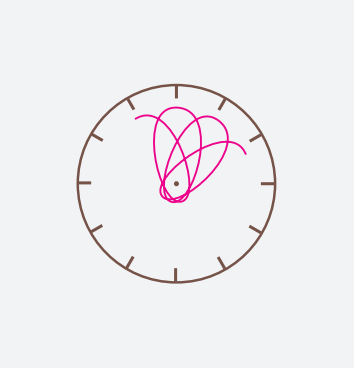

FIGURE 215 The trajectory of the middle point between the two ends of the hands of a clock

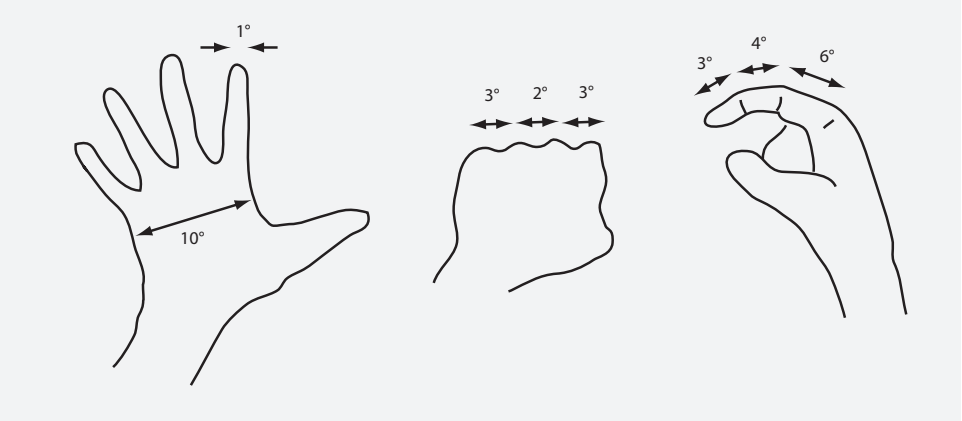

FIGURE 216 The angles defined by the hands against the sky, when the arms are extended

segments, you can make wooden blocks that can form an arch without any need for glue. The St. Louis arch is in shape of a catenary. A suspension bridge has the shape of a catenary before it is loaded, i.e., before the track is attached to it. When the bridge is finished, the shape is in between a catenary and a parabola.

Challenge 95, page 70: The inverse radii, or curvatures, obey $a^2 + b^2 + c^2 + d^2 = (1/2)(a + b + c + d)^2$. This formula was discovered by René Descartes. If one continues putting circles in the remaining spaces, one gets so-called circle packings, a pretty domain of recreational mathematics. They have many strange properties, such as intriguing relations between the coordinates of the circle centres and their curvatures.

Challenge 96, page 70: There are two solutions. (Why?) They are the two positive solutions of $l^2 = (b + x)^2 + (b + b^2/x)^2$; the height is then given as $h = b + x$. The two solutions are 4.84 m and 1.26 m. There are closed formulas for the solutions; can you find them?

Challenge 97, page 70: The best way is to calculate first the height B at which the blue ladder

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

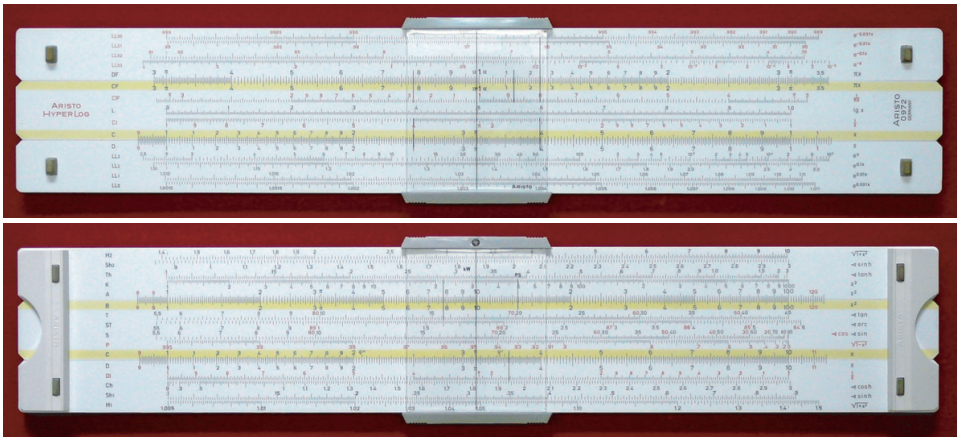

FIGURE 217 A high-end slide rule, around 1970 (© Jörn Lütjens)

touches the wall. It is given as a solution of $B^4 - 2hB^3 - (r^2 - b^2)B^2 + 2h(r^2 - b^2)B - h^2(r^2 - b^2) = 0$. Integer-valued solutions are discussed in MARTIN GARDNER, *Mathematical Circus*, Spectrum, 1996.

Challenge 98, page 70: Draw a logarithmic scale, i.e., put every number at a distance corresponding to its natural logarithm. Such a device, called a *slide rule*, is shown in Figure 217. Slide rules were the precursors of electronic calculators; they were used all over the world in prehistoric times, i.e., until around 1970. See also the web page www.oughtred.org.

Challenge 99, page 70: Two more. Build yourself a model of the Sun and the Earth to verify this.

Challenge 100, page 71: One option: use the three-dimensional analogue of Pythagoras's theorem. The answer is 9.

Challenge 101, page 71: The Sun is exactly behind the back of the observer; it is setting, and the rays are coming from behind and reach deep into the sky in the direction opposite to that of the Sun.

Challenge 103, page 71: The volume is given by $V = \int A\,dx = \int_{-1}^{1} 4(1 - x^2)\,dx = 16/3$.

Challenge 104, page 71: Yes. Try it with a paper model.

Challenge 105, page 72: Problems appear when quantum effects are added. A two-dimensional universe would have no matter, since matter is made of spin 1/2 particles. But spin 1/2 particles do not exist in two dimensions. Can you find other reasons?

Challenge 106, page 72: Two dimensions do not allow ordering of events. To say 'before' and 'afterwards' becomes impossible. In everyday life and all domains accessible to measurement, time is surely one-dimensional.

Challenge 108, page 74: From $x = gt^2/2$ you get the following rule: square the number of seconds, multiply by five and you get the depth in metres.

Challenge 109, page 74: Just experiment.

Challenge 110, page 74: The Academicians suspended one cannon ball with a thin wire just in front of the mouth of the cannon. When the shot was released, the second, flying cannon ball flew through the wire, thus ensuring that both balls started at the same time. An observer from far away then tried to determine whether both balls touched the Earth at the same time. The experiment is not easy, as small errors in the angle and air resistance confuse the results.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 111, page 75: A parabola has a so-called focus or focal point. All light emitted from that point and reflected exits in the same direction: all light ray are emitted in parallel. The name 'focus' – Latin for fireplace – expresses that it is the hottest spot when a parabolic mirror is illuminated. Where is the focus of the parabola $y = x^2$? (Ellipses have two foci, with a slightly different definition. Can you find it?)

Challenge 112, page 76: The long jump record could surely be increased by getting rid of the sand stripe and by measuring the true jumping distance with a photographic camera; that would allow jumpers to run more closely to their top speed. The record could also be increased by a small inclined step or by a spring-suspended board at the take-off location, to increase the take-off angle.

Challenge 113, page 76: Walk or run in the rain, measure your own speed v and the angle from the vertical α with which the rain appears to fall. Then the speed of the rain is $v_{\text{rain}} = v/\tan\alpha$.

Challenge 115, page 76: Neglecting air resistance and approximating the angle by 45°, we get $v = \sqrt{dg}$, or about 3.8 m/s. This speed is created by a stead pressure build-up, using blood pressure, which is suddenly released with a mechanical system at the end of the digestive canal. The cited reference tells more about the details.

Challenge 116, page 76: On horizontal ground, for a speed v and an angle from the horizontal α, neglecting air resistance and the height of the thrower, the distance d is $d = v^2 \sin 2\alpha/g$.

Challenge 117, page 76: Check your calculation with the information that the 1998 world record is juggling with 9 balls.

Challenge 118, page 76: It is said so, as rain drops would then be ice spheres and fall with high speed.

Challenge 119, page 77: There are conflicting statements in the literature. But it is a fact that people have gone to hospital because a falling bullet went straight through their head. (See S. Mirsky, It is high, it is far, *Scientific American* p. 86, February 2004.) In addition, the lead in bullets is bad for the environment.

Challenge 120, page 77: This is a true story. The answer can only be given if it is known whether the person had the chance to jump while running or not. In the case described by R. Cross, Forensic physics 101: falls from a height, *American Journal of Physics* **76**, pp. 833–837, 2008, there was no way to run, so that the answer was: murder.

Challenge 121, page 77: For jumps of an animal of mass m the necessary energy E is given as $E = mgh$, and the work available to a muscle is roughly speaking proportional to its mass $W \sim m$. Thus one gets that the height h is independent of the mass of the animal. In other words, the specific mechanical energyof animals is around 1.5 ± 0.7 J/kg.

Challenge 122, page 77: Stones never follow parabolas: when studied in detail, i.e., when the change of g with height is taken into account, their precise path turns out to be an ellipse. This shape appears most clearly for long throws, such as throws around a sizeable part of the Earth, or for orbiting objects. In short, stones follow parabolas only if the Earth is assumed to be flat. If its curvature is taken into account, they follow ellipses.

Challenge 123, page 78: The set of all rotations around a point in a plane is indeed a vector space. What about the set of all rotations around *all* points in a plane? And what about the three-dimensional cases?

Challenge 126, page 78: The scalar product between two vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ is given by

$$\boldsymbol{ab} = ab\cos\sphericalangle(\boldsymbol{a}, \boldsymbol{b}) \,. \tag{110}$$

How does this differ form the vector product?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 129, page 81: A candidate for low acceleration of a physical system might be the accelerations measured by gravitational wave detectors. They are below 10^{-13} m/s^2.

Challenge 130, page 81: In free fall (when no air is present) or inside a space station orbiting the Earth, one is accelerated but does not feel anything. In fact, this indistinguishability or equivalence between acceleration and 'feeling nothing' was an essential step for Albert Einstein in his development of general relativity.

Challenge 131, page 81: Professor to student: What is the derivative of velocity? Acceleration! What is the derivative of acceleration? I don't know. *Jerk*! The fourth, fifth and sixth derivatives of position are sometimes called *snap*, *crackle* and *pop*.

Challenge 133, page 83: One can argue that any source of light must have finite size.

Challenge 135, page 84: What the unaided human eye perceives as a tiny black point is usually about 50 µm in diameter.

Challenge 136, page 84: See page 741.

Challenge 137, page 84: One has to check carefully whether the conceptual steps that lead us to extract the concept of point from observations are correct. It will be shown in the final part of the adventure that this is not the case.

Challenge 138, page 85: One can rotate the hand in a way that the arm makes the motion described. See also page 1067.

Challenge 139, page 85: Any number, without limit.

Challenge 140, page 85: The blood and nerve supply is not possible if the wheel has an axle. The method shown to avoid tangling up connections only works when the rotating part has *no* axle: the 'wheel' must float or be kept in place by other means. It thus becomes impossible to make a wheel *axle* using a single piece of skin. And if a wheel without an axle could be built (which might be possible), then the wheel would periodically run over the connection. Could such a axle-free connection realize a propeller?

By the way, it is still thinkable that animals have wheels on axles, if the wheel is a 'dead' object. Even if blood supply technologies like continuous flow reactors were used, animals could not make such a detached wheel grow in a way tuned to the rest of the body and they would have difficulties repairing a damaged wheel. Detached wheels cannot be grown on animals; they must be dead.

Challenge 141, page 86: The brain in the skull, the blood factories inside bones or the growth of the eye are examples.

Challenge 142, page 87: In 2007, the largest big wheels for passengers are around 150 m in diameter. The largest wind turbines are around 125 m in diameter. Cement kilns are the longest wheels: they can be over 300 m along their axis.

Challenge 143, page 87: Air resistance reduces the maximum distance, which is achieved for an angle of about $\pi/4 = 45°$, from around $v^2/g = 91.7$ m down to around 50 m.

Challenge 147, page 89: One can also add the Sun, the sky and the landscape to the list.

Challenge 148, page 90: Ghosts, hallucinations, Elvis sightings, or extraterrestrials must all be one or the other. There is no third option. Even shadows are only special types of images.

Challenge 149, page 90: The issue was hotly discussed in the seventeenth century; even Galileo argued for them being images. However, they are objects, as they can collide with other objects, as the spectacular collision between Jupiter and the comet Shoemaker-Levy 9 in 1994 showed. In the meantime, satellites have been made to collide with comets and even to shoot at them (and hitting).

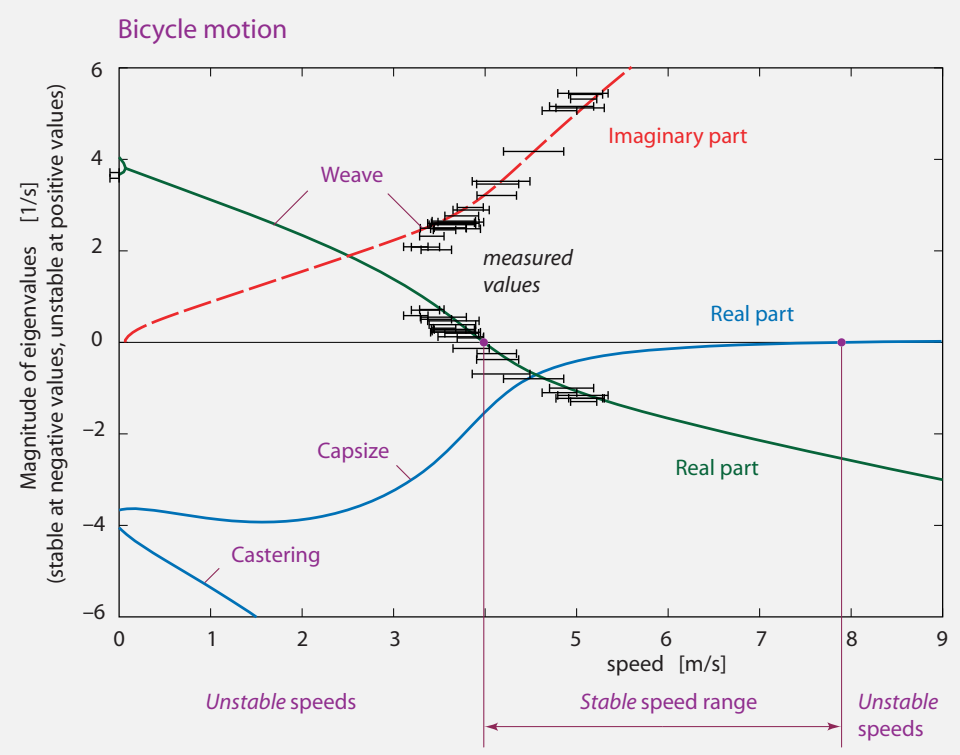

FIGURE 218 The measured (black bars) and calculated behaviour (coloured lines) – more precisely, the dynamical eigenvalues – of a bicycle as a function of its speed (© Arend Schwab)

Challenge 150, page 91: The minimum speed is roughly the one at which it is possible to ride without hands. If you do so, and then *gently* push on the steering wheel, you can make the experience described above. Watch out: too strong a push will make you fall badly.

The *bicycle* is one of the most complex mechanical systems of everyday life, and it is still a subject of research. And obviously, the world experts are Dutch. An overview of the behaviour of a bicycle is given in Figure 218. The main result is that the bicycle is stable in the upright position at a range of medium speeds. Only at low and at large speeds must the rider actively steer to ensure upright position of the bicycle.

For more details, see J. P. Meijaard, J. M. Papadopoulos, A. Ruina & A. L. Schwab, Linearized dynamics equations for the balance and steer of a bicycle: a benchmark and review, *Proceedings of the Royal Society A* **463**, pp. 1955–1982, 2007, and J. D. G. Kooijman, A. L. Schwab & J. P. Meijaard, Experimental validation of a model of an uncontrolled bicycle, *Multibody System Dynamics* **19**, pp. 115–132, 2008. See also the audiophile.tam.cornell.edu/~als93/Bicycle/index.htm website.

Challenge 151, page 93: If the moving ball is not rotating, after the collision the two balls will depart with a *right* angle between them.

Challenge 152, page 94: Part of the energy is converted into heat; the rest is transferred as kinetic energy of the concrete block. As the block is heavy, its speed is small and easily stopped by the human body. This effect works also with anvils, it seems. In another common variation the person does not lie on nails, but on air: he just keeps himself horizontal, with head and shoulders

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

on one chair, and the feet on a second one.

Challenge 153, page 95: Yes, mass works also for magnetism, because the precise condition is not that the interaction be central, but that it realizes a more general condition, which includes accelerations such as those produced by magnetism. Can you deduce the condition from the definition of mass?

Challenge 154, page 95: The weight decreased due to the evaporated water lost by sweating and, to a minor degree, due to the exhaled carbon bound in carbon dioxide.

Challenge 155, page 95: Rather than using the inertial effects of the Earth, it is easier to deduce its mass from its gravitational effects. See challenge 268.

Challenge 159, page 97: At first sight, relativity implies that tachyons have imaginary mass; however, the imaginary factor can be extracted from the mass–energy and mass–momentum relation, so that one can define a real mass value for tachyons; as a result, faster tachyons have smaller energy and smaller momentum. Both momentum and energy can be a negative number of any size.

Challenge 160, page 98: Legs are never perfectly vertical; they would immediately glide away. Once the cat or the person is on the floor, it is almost impossible to stand up again.

Challenge 161, page 98: Momentum (or centre of mass) conservation would imply that the environment would be accelerated into the opposite direction. Energy conservation would imply that a huge amount of energy would be transferred between the two locations, melting everything in between. Teleportation would thus contradict energy and momentum conservation.

Challenge 162, page 99: The part of the tides due to the Sun, the solar wind, and the interactions between both magnetic fields are examples of friction mechanisms between the Earth and the Sun.

Challenge 163, page 100: With the factor 1/2, increase of (physical) kinetic energy is equal to the (physical) work performed on a system: total energy is thus conserved only if the factor 1/2 is added.

Challenge 165, page 101: It is a smart application of momentum conservation.

Challenge 166, page 101: Neither. With brakes on, the damage is higher, but still equal for both cars.

Challenge 167, page 102: Heating systems, transport engines, engines in factories, steel plants, electricity generators covering the losses in the power grid, etc. By the way, the richest countries in the world, such as Sweden or Switzerland, consume only half the energy per inhabitant as the USA. This waste is one of the reasons for the lower average standard of living in the USA.

Challenge 169, page 104: Just throw it into the air and compare the dexterity needed to make it turn around various axes.

Challenge 170, page 105: Use the definition of the moment of inertia and Pythagoras' theorem for every mass element of the body.

Challenge 171, page 105: Hang up the body, attaching the rope in two different points. The crossing point of the prolonged rope lines is the centre of mass.

Challenge 173, page 106: Spheres have an orientation, because we can always add a tiny spot on their surface. This possibility is not given for microscopic objects, and we shall study this situation in the part on quantum theory.

Challenge 172, page 106: See Tables 19 and 20.

Challenge 176, page 107: Self-propelled linear motion contradicts the conservation of momentum; self-propelled change of orientation (as long as the motion stops again) does not contradict

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

any conservation law. But the deep, final reason for the difference will be unveiled in the final part of our adventure.

Challenge 177, page 107: Yes, the ape can reach the banana. The ape just has to turn around its own axis. For every turn, the plate will rotate a bit towards the banana. Of course, other methods, like blowing at a right angle to the axis, peeing, etc., are also possible.

Challenge 179, page 108: The points that move exactly along the radial direction of the wheel form a circle below the axis and above the rim. They are the points that are sharp in Figure 65 of page 107.

Challenge 180, page 108: Use the conservation of angular momentum around the point of contact. If all the wheel's mass is assumed in the rim, the final rotation speed is half the initial one; it is independent of the friction coefficient.

Challenge 182, page 109: Probably the 'rest of the universe' was meant by the writer. Indeed, a moving a part never shifts the centre of gravity of a closed system. But is the universe closed? Or a system? The last part of our adventure covers these issues.

Challenge 183, page 109: Hint: an energy per distance is a force.

Challenge 184, page 110: The conservation of angular momentum saves the glass. Try it.

Challenge 185, page 110: First of all, MacDougall's experimental data is flawed. In the six cases MacDougall examined, he did not know the exact timing of death. His claim of a mass decrease cannot be deduced from his own data. Modern measurements on dying sheep, about the same mass as humans, have shown no mass change, but clear weight pulses of a few dozen grams when the heart stopped. This temporary weight decrease could be due to the expelling of air or moisture, to the relaxing of muscles, or to the halting of blood circulation. The question is not settled.

Challenge 186, page 110: Assuming a square mountain, the height h above the surrounding crust and the depth d below are related by

$$\frac{h}{d} = \frac{\rho_m - \rho_c}{\rho_c} \tag{111}$$

where ρ_c is the density of the crust and ρ_m is the density of the mantle. For the density values given, the ratio is 6.7, leading to an additional depth of 6.7 km below the mountain.

Challenge 188, page 111: The behaviour of the spheres can only be explained by noting that elastic waves propagate through the chain of balls. Only the propagation of these elastic waves, in particular their reflection at the end of the chain, explains that the same number of balls that hit on one side are lifted up on the other. For long times, friction makes all spheres oscillate in phase. Can you confirm this?

Challenge 189, page 112: When the short cylinder hits the long one, two compression waves start to run from the point of contact through the two cylinders. When each compression wave arrives at the end, it is reflected as an expansion wave. If the geometry is well chosen, the expansion wave coming back from the short cylinder can continue into the long one (which is still in his compression phase). For sufficiently long contact times, waves from the short cylinder can thus depose much of their energy into the long cylinder. Momentum is conserved, as is energy; the long cylinder is oscillating in length when it detaches, so that not all its energy is translational energy. This oscillation is then used to drive nails or drills into stone walls. In commercial hammer drills, length ratios of 1:10 are typically used.

Challenge 190, page 112: The momentum transfer to the wall is double when the ball rebounds perfectly.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 191, page 112: If the cork is in its intended position: take the plastic cover off the cork, put the cloth around the bottle (this is for protection reasons only) and repeatedly hit the bottle on the floor or a fall in an inclined way, as shown in Figure 59 on page 98. With each hit, the cork will come out a bit.

If the cork has fallen inside the bottle: put half the cloth inside the bottle; shake until the cork falls unto the cloth. Pull the cloth out: first slowly, until the cloth almost surround the cork, and then strongly.

Challenge 193, page 113: The atomic force microscope.

Challenge 195, page 113: Running man: $E \approx 0.5 \cdot 80\,\mathrm{kg} \cdot (5\,\mathrm{m/s})^2 = 1\,\mathrm{kJ}$; rifle bullet: $E \approx 0.5 \cdot 0.04\,\mathrm{kg} \cdot (500\,\mathrm{m/s})^2 = 5\,\mathrm{kJ}$.

Challenge 196, page 113: It almost doubles in size.

Challenge 197, page 113: At the highest point, the acceleration is $g \sin\alpha$, where α is the angle of the pendulum at the highest point. At the lowest point, the acceleration is v^2/l, where l is the length of the pendulum. Conservation of energy implies that $v^2 = 2gl(1 - \cos\alpha)$. Thus the problem requires that $\sin\alpha = 2(1 - \cos\alpha)$. This results in $\cos\alpha = 3/5$.

Challenge 198, page 113: One needs the mass change equation $\mathrm{d}m/\mathrm{d}t = \pi\rho_{\mathrm{vapour}} r^2 |v|$ due to the vapour and the drop speed evolution $m\,\mathrm{d}v/\mathrm{d}t = mg - v\,\mathrm{d}m/\mathrm{d}t$. These two equations yield

$$\frac{\mathrm{d}v^2}{\mathrm{d}r} = \frac{2g}{C} - 6\frac{v^2}{r} \tag{112}$$

where $C = \rho_{\mathrm{vapour}}/4\rho_{\mathrm{water}}$. The trick is to show that this can be rewritten as

$$r\frac{\mathrm{d}}{\mathrm{d}r}\frac{v^2}{r} = \frac{2g}{C} - 7\frac{v^2}{r}\,. \tag{113}$$

For large times, all physically sensible solutions approach $v^2/r = 2g/7C$; this implies that for large times,

$$\frac{\mathrm{d}v}{\mathrm{d}t}\frac{v^2}{r} = \frac{g}{7} \quad \text{and} \quad r = \frac{gC}{14}t^2\,. \tag{114}$$

About this famous problem, see for example, B. F. Edwards, J. W. Wilder & E. E. Scime, Dynamics of falling raindrops, *European Journal of Physics* **22**, pp. 113–118, 2001.

Challenge 201, page 114: Weigh the bullet and shoot it against a mass hanging from the ceiling. From the mass and the angle it is deflected to, the momentum of the bullet can be determined.

Challenge 203, page 114: The curve described by the midpoint of a ladder sliding down a wall is a circle.

Challenge 204, page 114: The switched use the power that is received when the switch is pushed and feed it to a small transmitter that acts a high frequency remote control to switch on the light.

Challenge 205, page 114: A clever arrangement of bimetals is used. They move every time the temperature changes from day to night – and vice versa – and wind up a clock spring. The clock itself is a mechanical clock with low energy consumption.

Challenge 207, page 118: The Coriolis effect can be seen as the sum two different effects of equal magnitude. The first effect is the following: on a rotating background, velocity changes time. What an inertial (nonrotating) observer sees as a constant velocity will be seen a velocity changing in time by the rotating observer. The acceleration seen by the rotating observer is negative, and proportional to the angular velocity and to the velocity.

The second effect is change of velocity in space. In a rotating frame of reference, different points have different velocities. The effect is negative, and proportional to the angular velocity and to the velocity.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In total, the Coriolis acceleration (or Coriolis effect) is thus $\boldsymbol{a}_C = -2\boldsymbol{\omega} \times \boldsymbol{v}$.

Challenge 208, page 119: A *short* pendulum of length L that swings in two dimensions (with amplitude ρ and orientation φ) shows two additional terms in the Lagrangian $\mathcal{L}$:

$$\mathcal{L} = T - V = \frac{1}{2}m\dot{\rho}^2(1 + \frac{\rho^2}{L^2}) + \frac{l_z^2}{2m\rho^2} - \frac{1}{2}m\omega_0^2\rho^2(1 + \frac{\rho^2}{4\,L^2}) \tag{115}$$

where as usual the basic frequency is $\omega_0^2 = g/L$ and the angular momentum is $l_z = m\rho^2\dot{\varphi}$. The two additional terms disappear when $L \to \infty$; in that case, if the system oscillates in an ellipse with semiaxes a and b, the ellipse is fixed in space, and the frequency is ω_0. For *finite* pendulum length L, the frequency changes to

$$\omega = \omega_0(1 - \frac{a^2 + b^2}{16\,L^2}) \quad ; \tag{116}$$

most of all, the ellipse turns with a frequency

$$\Omega = \omega\frac{3}{8}\frac{ab}{L^2}\,. \tag{117}$$

These formulae can be derived using the least action principle, as shown by C. G. Gray, G. Karl & V. A. Novikov, Progress in classical and quantum variational principles, arxiv.org/abs/physics/0312071. In other words, a short pendulum in elliptical motion shows a precession even *without* the Coriolis effect. Since this precession frequency diminishes with $1/L^2$, the effect is small for long pendulums, where only the Coriolis effect is left over. To see the Coriolis effect in a short pendulum, one thus has to avoid that it starts swinging in an elliptical orbit by adding a suppression method of elliptical motion.

Challenge 209, page 119: The Coriolis acceleration is the reason for the deviation from the straight line. The Coriolis acceleration is due to the change of speed with distance from the rotation axis. Now think about a pendulum, located in Paris, swinging in the North-South direction with amplitude A. At the Southern end of the swing, the pendulum is further from the axis by $A \sin\varphi$, where φ is the latitude. At that end of the swing, the central support point overtakes the pendulum bob with a relative horizontal speed given by $v = 2\pi A \sin\varphi/23\,\mathrm{h}56\,\mathrm{min}$. The period of precession is given by $T_F = v/2\pi A$, where $2\pi A$ is the circumference $2\pi A$ of the envelope of the pendulum's path (relative to the Earth). This yields $T_F = 23\,\mathrm{h}56\,\mathrm{min}/\sin\varphi$. Why is the value that appears in the formula not 24 h, but 23 h56 min?

Challenge 210, page 120: The axis stays fixed with respect to distant stars, not with respect to absolute space (which is an entity that cannot be observed at all).

Challenge 211, page 120: Rotation leads to a small frequency and thus colour changes of the circulating light.

Challenge 212, page 120: The weight changes when going east or when moving west due to the Coriolis acceleration. If the rotation speed is tuned to the oscillation frequency of the balance, the effect is increased by resonance. This trick was also used by Eötvös.

Challenge 213, page 121: The Coriolis acceleration makes the bar turn, as every moving body is deflected to the side, and the two deflections add up in this case. The direction of the deflection depends on whether the experiments is performed on the northern or the southern hemisphere.

Challenge 214, page 121: When rotated by π around an east–west axis, the Coriolis force produces a drift velocity of the liquid around the tube. It has the value

$$v = 2\omega r \sin\theta, \tag{118}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

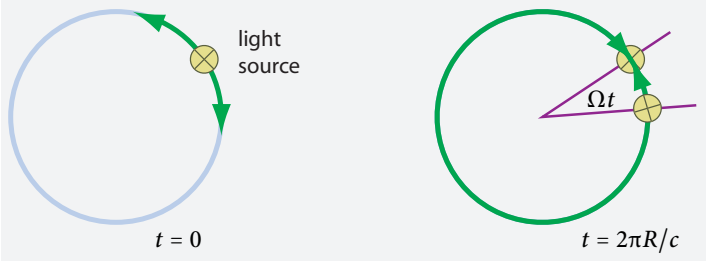

FIGURE 219 Deducing the expression for the Sagnac effect

as long as friction is negligible. Here ω is the angular velocity of the Earth, θ the latitude and r the (larger) radius of the torus. For a tube with 1 m diameter in continental Europe, this gives a speed of about $6.3 \cdot 10^{-5}$ m/s.

The measurement can be made easier if the tube is restricted in diameter at one spot, so that the velocity is increased there. A restriction by an area factor of 100 increases the speed by the same factor. When the experiment is performed, one has to carefully avoid any other effects that lead to moving water, such as temperature gradients across the system.

Challenge 215, page 121: Imagine a circular light path (for example, inside a circular glass fibre) and two beams moving in opposite directions along it, as shown in Figure 219. If the fibre path rotates with rotation frequency Ω, we can deduce that, after one turn, the difference ΔL in path length is

$$\Delta L = 2R\Omega t = \frac{4\pi R^2 \Omega}{c} \,. \tag{119}$$

The phase difference is thus

$$\Delta\varphi = \frac{8\pi^2 \, R^2}{c\,\lambda}\Omega \tag{120}$$

if the refractive index is 1. This is the required formula for the main case of the Sagnac effect.

Challenge 216, page 122: The metal rod is slightly longer on one side of the axis. When the wire keeping it up is burned with a candle, its moment of inertia decreases by a factor of 10^4; thus it starts to rotate with (ideally) 10^4 times the rotation rate of the Earth, a rate which is easily visible by shining a light beam on the mirror and observing how its reflection moves on the wall.

Challenge 217, page 128: The original result by Bessel was 0.3136″, or 657.7 thousand orbital radii, which he thought to be 10.3 light years or 97.5 Pm.

Challenge 219, page 131: The galaxy forms a stripe in the sky. The galaxy is thus a flattened structure. This is even clearer in the infrared, as shown more clearly in Figure 293 on page 565. From the flattening (and its circular symmetry) we can deduce that the galaxy must be rotating. Thus other matter must exist in the universe.

Challenge 221, page 133: If the Earth changed its rotation speed ever so slightly we would walk inclined, the water of the oceans would flow north, the atmosphere would be filled with storms and earthquakes would appear due to the change in Earth's shape.

Challenge 223, page 134: The scale reacts to your heartbeat. The weight is almost constant over time, except when the heart beats: for a short duration of time, the weight is somewhat lowered at each beat. Apparently it is due to the blood hitting the aortic arch when the heart pumps it upwards. The speed of the blood is about 0.3 m/s at the maximum contraction of the left ventricle. The distance to the aortic arch is a few centimetres. The time between the contraction and the reversal of direction is about 15 ms.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 224, page 134: Use Figure 78 on page 118 for the second half of the trajectory, and think carefully about the first half.

Challenge 225, page 134: Hint: starting rockets at the Equator saves a lot of energy, thus of fuel and of weight.

Challenge 226, page 135: The flame leans towards the inside.

Challenge 227, page 135: The ball leans in the direction it is accelerated to. As a result, one could imagine that the ball in a glass at rest pulls upwards because the floor is accelerated upwards. We will come back to this issue in the section of general relativity.

Challenge 229, page 135: For your exam it is better to say that centrifugal force does not exist. But since in each stationary system there is a force balance, the discussion is somewhat a red herring.

Challenge 231, page 135: Place the tea in cups on a board and attach the board to four long ropes that you keep in your hand.

Challenge 232, page 135: The friction if the tides on Earth are the main cause.

Challenge 233, page 136: An earthquake with Richter magnitude of 12 is 1000 times the energy of the 1960 Chile quake with magnitude 10; the latter was due to a crack throughout the full 40 km of the Earth's crust along a length of 1000 km in which both sides slipped by 10 m with respect to each other. Only the impact of a meteorite could lead to larger values than 12.

Challenge 234, page 136: This is not easy; a combination of friction and torques play a role. See for example the article J. Sauer, E. Schörner & C. Lennerz, Real-time rigid body simulation of some classical mechanical toys, 10th European Simulation and Symposium and Exhibition (ESS '98) 1998, pp. 93–98, or http//www.lennerz.de/paper_ess98.pdf.

Challenge 236, page 136: If a wedding ring rotates on an axis that is not a principal one, angular momentum and velocity are not parallel.

Challenge 237, page 136: Yes; it happens twice a year. To minimize the damage, dishes should be dark in colour.

Challenge 238, page 137: A rocket fired from the back would be a perfect defence against planes attacking from behind. However, when released, the rocket is effectively flying backwards with respect to the air, thus turns around and then becomes a danger to the plane that launched it. Engineers who did not think about this effect almost killed a pilot during the first such tests.

Challenge 239, page 137: Whatever the ape does, whether it climbs up or down or even lets himself fall, it remains at the same height as the mass. Now, what happens if there is friction at the wheel?

Challenge 240, page 137: Yes, if he moves at a large enough angle to the direction of the boat's motion.

Challenge 242, page 137: The moment of inertia is $\Theta = \frac{2}{5}mr^2$.

Challenge 243, page 137: The moments of inertia are equal also for the cube, but the values are $\Theta = \frac{1}{6}ml^2$. The efforts required to put a sphere and a cube into rotation are thus different.

Challenge 244, page 137: See the article by C. Ucke & H.-J. Schlichting, Faszinierendes Dynabee, *Physik in unserer Zeit* **33**, pp. 230–231, 2002.

Challenge 245, page 138: See the article by C. Ucke & H.-J. Schlichting, Die kreisende Büroklammer, *Physik in unserer Zeit* **36**, pp. 33–35, 2005.

Challenge 246, page 138: Yes. Can you imagine what happens for an observer on the Equator?

Challenge 247, page 138: A straight line at the zenith, and circles getting smaller at both sides. See an example on the website antwrp.gsfc.nasa.gov/apod/ap021115.html.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 249, page 139: The plane is described in the websites cited; for a standing human the plane is the vertical plane containing the two eyes.

Challenge 250, page 139: As said before, legs are simpler than wheels to grow, to maintain and to repair; in addition, legs do not require flat surfaces (so-called 'streets') to work.

Challenge 251, page 141: The staircase formula is an empirical result found by experiment, used by engineers world-wide. Its origin and explanation seems to be lost in history.

Challenge 252, page 141: Classical or everyday nature is right-left symmetric and thus requires an even number of legs. Walking on two-dimensional surfaces naturally leads to a minimum of four legs.

Challenge 254, page 142: The length of the day changes with latitude. So does the length of a shadow or the elevation of stars at night, facts that are easily checked by telephoning a friend. Ships appear at the horizon first be showing only their masts. These arguments, together with the round shadow of the earth during a lunar eclipse and the observation that everything falls downwards everywhere, were all given already by Aristotle, in his text *On the Heavens*. It is now known that everybody in the last 2500 years knew that the Earth is s sphere. The myth that many people used to believe in a flat Earth was put into the world – as rhetorical polemic – by Copernicus. The story then continued to be exaggerated more and more during the following centuries, because a new device for spreading lies had just been invented: book printing. Fact is that since 2500 years the vast majority of people knew that the Earth is a sphere.

Page 848

Challenge 255, page 142: Robert Peary had forgotten that on the date he claimed to be at the North Pole, 6th of April 1909, the Sun is very low on the horizon, casting very long shadows, about ten times the height of objects. But on his photograph the shadows are much shorter. (In fact, the picture is taken in such a way to hide all shadows as carefully as possible.) Interestingly, he had even convinced the US congress to officially declare him the first man on the North Pole in 1911. (A rival crook had claimed to have reached it before Peary, but his photograph has the same mistake.) Peary also cheated on the travelled distances of the last few days; he also failed to mention that the last days he was pulled by his partner, Matthew Henson, because he was not able to walk any more. In fact Matthew Henson deserves more credit for that adventure than Peary. Henson, however, did not know that Peary cheated on the position they had reached.

Challenge 256, page 142: Yes, the effect has been measured for skyscrapers. Can you estimate the values?

Challenge 257, page 144: The tip of the velocity arrow, when drawn over time, produces a circle around the centre of motion.

Challenge 258, page 144: Draw a figure of the situation.

Challenge 259, page 144: Again, draw a figure of the situation.

Challenge 260, page 144: The value of the product GM for the Earth is $4.0 \cdot 10^{14}\,\mathrm{m^3/s^2}$.

Challenge 261, page 145: All points can be reached for general inclinations; but when shooting horizontally in one given direction, only points on the first half of the circumference can be reached.

Challenge 263, page 146: On the moon, the gravitational acceleration is $1.6\,\mathrm{m/s^2}$, about one sixth of the value on Earth. The surface values for the gravitational acceleration for the planets can be found on many internet sites.

Challenge 264, page 146: The Atwood machine is the answer: two almost equal masses m_1 and m_2 connected by a string hanging from a well-oiled wheel of negligible mass. The heavier one falls very slowly. Can show that the acceleration a of this 'unfree' fall is given by $a = g(m_1 - m_2)/(m_1 + m_2)$? In other words, the smaller the mass difference is, the slower the fall is.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 265, page 146: You should absolutely try to understand the origin of this expression. It allows to understand many essential concepts of mechanics. The idea is that for small amplitudes, the acceleration of a pendulum of length l is due to gravity. Drawing a force diagram for a pendulum at a general angle α shows that

$$\begin{aligned} ma &= -mg\sin\alpha \\ ml\frac{\mathrm{d}^2\alpha}{\mathrm{d}t^2} &= -mg\sin\alpha \\ l\frac{\mathrm{d}^2\alpha}{\mathrm{d}t^2} &= -g\sin\alpha\ . \end{aligned} \tag{121}$$

For the mentioned small amplitudes (below 15°) we can approximate this to

$$l\frac{\mathrm{d}^2\alpha}{\mathrm{d}t^2} = -g\alpha\ . \tag{122}$$

This is the equation for a harmonic oscillation (i.e., a sinusoidal oscillation). The resulting motion is:

$$\alpha(t) = A\sin(\omega t + \varphi)\ . \tag{123}$$

The amplitude A and the phase φ depend on the initial conditions; however, the oscillation frequency is given by the length of the pendulum and the acceleration of gravity (check it!):

$$\omega = \sqrt{\frac{l}{g}}\ . \tag{124}$$

(For arbitrary amplitudes, the formula is much more complex; see the internet or special mechanics books for more details.)

Challenge 266, page 146: Walking speed is proportional to l/T, which makes it proportional to $l^{1/2}$. The relation is also true for animals in general. Indeed, measurements show that the maximum walking speed (thus not the running speed) across all animals is given by

$$v_{\mathrm{maxwalking}} = (2.2 \pm 0.2)\,\mathrm{m}^{1/2}/\mathrm{s}\,\sqrt{l}\ . \tag{125}$$

Challenge 268, page 148: Cavendish suspended a horizontal handle with a long metal wire. He then approached a large mass to the handle, avoiding any air currents, and measured how much the handle rotated.

Challenge 269, page 148: The acceleration due to gravity is $a = Gm/r^2 \approx 5\,\mathrm{nm/s^2}$ for a mass of 75 kg. For a fly with mass $m_{\mathrm{fly}} = 0.1\,\mathrm{g}$ landing on a person with a speed of $v_{\mathrm{fly}} = 1\,\mathrm{cm/s}$ and deforming the skin (without energy loss) by $d = 0.3\,\mathrm{mm}$, a person would be accelerated by $a = (v^2/d)(m_{\mathrm{fly}}/m) = 0.4\,\mu\mathrm{m/s^2}$. The energy loss of the inelastic collision reduces this value at least by a factor of ten.

Challenge 271, page 149: The easiest way to see this is to picture gravity as a flux emanating form a sphere. This gives a $1/r^{d-1}$ dependence for the force and thus a $1/r^{d-2}$ dependence of the potential.

Challenge 273, page 151: Since the paths of free fall are ellipses, which are curves lying in a plane, this is obvious.

Challenge 274, page 152: See page 155.

Challenge 275, page 153: The low gravitational acceleration of the Moon, $1.6\,\mathrm{m/s^2}$, implies that gas molecules at usual temperatures can escape its attraction.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 220 The famous 'vomit comet', a KC-135, performing a parabolic flight (NASA)

Challenge 277, page 154: A flash of light is sent to the Moon, where several Cat's-eyes have been deposited by the Lunokhod and Apollo missions. The measurement precision of the time a flash take to go and come back is sufficient to measure the Moon's distance change. For more details, see challenge 618.

Challenge 282, page 157: The Lagrangian points L4 and L5 are on the orbit, 60° before and behind the orbiting body. They are stable if the mass ratio of the central and the orbiting body is sufficiently large (above 24.9)

Challenge 283, page 157: The Lagrangian point L3 is located on the orbit, but precisely on the other side of the central body. The Lagrangian point L1 is located on the line connecting the planet with the central body, whereas L2 lies outside the orbit, on the same line. If R is the radius of the orbit, the distance between the orbiting body and the L1 and L2 point is $\sqrt[3]{m/3M}\,R$, giving around 4 times the distance of the Moon for the Sun-Earth system. L1, L2 and L3 are saddle points, but effectively stable orbits exist around them. Many satellites make use of these properties, including the famous WMAP satellite that measured the ripples of the big bang, which is located at L2.

Challenge 284, page 159: This is a resonance effect, in the same way that a small vibration of a string can lead to large oscillation of the air and sound box in a guitar.

Challenge 286, page 160: The expression for the strength of tides, namely $2GM/d^3$, can be rewritten as $(8/3)\pi G\rho(R/d)^3$. Now, R/d is roughly the same for Sun and Moon, as every eclipse shows. So the density ρ must be much larger for the Moon. In fcat, the ratio of the strengths (height) of the tides of Moon and Sun is roughly 7 : 3. This is also the ratio between the mass densities of the two bodies.

Challenge 287, page 160: The total angular momentum of the Earth and the Moon must remain constant.

Challenge 292, page 164: Either they fell on inclined snowy mountain sides, or they fell into high trees, or other soft structures. The record was over 7 km of survived free fall. A recent case made the news in 2007 and is told in www.bbc.co.uk/jersey/content/articles/2006/12/20/michael_holmes_fall_feature.shtml.

Challenge 294, page 165: For a few thousand Euros, you can experience zero-gravity in a parabolic flight, such as the one shown in Figure 220. (Many 'photographs' of parabolic flights found on the internet are in fact computer graphics. What about this one?)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 295, page 165: The centre of mass of a broom falls with the usual acceleration; the end thus falls faster.

Challenge 296, page 165: Just use energy conservation for the two masses of the jumper and the string. For more details, including the comparison of experimental measurements and theory, see N. Dubelaar & R. Brantjes, De valversnelling bij bungee-jumping, *Nederlands tijdschrift voor natuurkunde* **69**, pp. 316–318, October 2003.

Challenge 297, page 165: About 1 ton.

Challenge 298, page 165: About 5 g.

Challenge 299, page 166: Your weight is roughly constant; thus the Earth must be round. On a flat Earth, the weight would change from place to place, depending on your distance from the border.

Challenge 300, page 166: Nobody ever claimed that the centre of mass is the same as the centre of gravity! The attraction of the Moon is negligible on the surface of the Earth.

Challenge 302, page 167: That is the mass of the Earth. Just turn the table on its head.

Challenge 304, page 167: The Moon will be about 1.25 times as far as it is now. The Sun then will slow down the Earth–Moon system rotation, this time due to the much smaller tidal friction from the Sun's deformation. As a result, the Moon will return to smaller and smaller distances to Earth. However, the Sun will have become a red giant by then, after having swallowed both the Earth and the Moon.

Challenge 306, page 167: As Galileo determined, for a swing (half a period) the ratio is $\sqrt{2}/\pi$. (See challenge 265). But not more than two, maybe three decimals of π can be determined in this way.

Challenge 307, page 168: Momentum conservation is not a hindrance, as any tennis racket has the same effect on the tennis ball.

Challenge 308, page 168: In fact, in velocity space, elliptic, parabolic and hyperbolic motions are all described by circles. In all cases, the hodograph is a circle.
Ref. 131

Challenge 309, page 168: This question is old (it was already asked in Newton's times) and deep. One reason is that stars are kept apart by rotation around the galaxy. The other is that galaxies are kept apart by the momentum they got in the big bang. Without the big bang, all stars would have collapsed together. In this sense, the big bang can be deduced from the attraction of gravitation and the immobile sky at night. We shall find out later that the darkness of the night sky gives a second argument for the big bang.

Challenge 310, page 168: Due to the plateau, the effective mass of the Earth is larger.

Challenge 311, page 168: The choice is clear once you notice that there is no section of the orbit which is concave towards the Sun. Can you show this?

Challenge 312, page 169: It would be a black hole; no light could escape. Black holes are discussed in detail in the chapter on general relativity.
Page 604

Challenge 313, page 169: A handle of two bodies.

Challenge 316, page 169: Using a maximal jumping height of h =0.5 m on Earth and an estimated asteroid density of ρ =3 Mg/m^3, we get a maximum radius of $R^2 = 3gh/4\pi G\rho \approx 703$ m.

Challenge 317, page 170: The shape of an analemma at local noon is shown in Figure 221. The vertical extension of the analemma is due to the obliquity, i.e., the tilt of the Earth's axis (it is twice 23.45°). The horizontal extension is due to the combination of the obliquity and of the ellipticity of the orbit around the Sun. Both effects change the speed of the Earth along its orbit, leading to changes of the position of the Sun at local noon during the course of the year. The asymmetrical

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 221 The analemma photographed, at local noon, from January to December 2002, at the Parthenon on Athen's Acropolis, and a precision sundial (© Anthony Ayiomamitis, Stefan Pietrzik)

position of the central crossing point The shape of the analemma is also built into the shadow pole of precision sundials.

Challenge 318, page 171: Capture of a fluid body if possible if it is split by tidal forces.

Challenge 319, page 171: The tunnel would be an elongated ellipse in the plane of the Equator, reaching from one point of the Equator to the point at the antipodes. The time of revolution would not change, compared to a non-rotating Earth. See A. J. Simonson, Falling down a hole through the Earth, *Mathematics Magazine* 77, pp. 171–188, June 2004.

Challenge 321, page 171: The centre of mass of the solar system can be as far as twice the radius from the centre of the Sun; it thus can be outside the Sun.

Challenge 322, page 172: First, during northern summer time the Earth moves faster around the Sun than during northern winter time. Second, shallow Sun's orbits on the sky give longer days because of light from when the Sun is below the horizon.

Challenge 323, page 172: Apart from the visibility of the Moon, no effect on humans has ever been detected. Gravitational effects – including tidal effects – electrical effects, magnetic effects and changes in cosmic rays are all swamped by other effects. Indeed the gravity of passing trucks, factory electromagnetic fields, the weather and solar activity changes have larger influences on humans than th Moon. The locking of the menstrual cycle to the moon phase is a visual effect.

Challenge 324, page 172: Distances were difficult to measure. It is easy to observe a planet that is before the Sun, but it is hard to check whether a planet is behind the Sun.

Challenge 325, page 172: See the mentioned reference.

Challenge 326, page 172: True.

Challenge 327, page 173: For each pair of opposite shell elements (drawn in yellow), the two attractions compensate.

Challenge 328, page 173: There is no practical way; if the masses on the shell could move, along the surface (in the same way that charges can move in a metal) this might be possible, provided that enough mass is available.

Challenge 331, page 173: Yes, one could, and this has been thought of many times, including by Jules Verne. The necessary speed depends on the direction of the shot with respect of the rotation of the Earth.

Challenge 332, page 173: Never. The Moon points always towards the Earth. The Earth changes position a bit, due to the ellipticity of the Moon's orbit. Obviously, the Earth shows phases.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 334, page 174: What counts is *local* verticality; with respect to it, the river always flows downhill.

Challenge 335, page 174: There are no such bodies, as the chapter of general relativity will show.

Challenge 337, page 176: The oscillation is a purely sinusoidal, or harmonic oscillation, as the restoring force increases linearly with distance from the centre of the Earth. The period T for a homogeneous Earth is $T = 2\pi\sqrt{R^3/GM} = 84\,\text{min}$.

Challenge 338, page 176: The period is the same for all such tunnels and thus in particular it is the same as the 84 min valid also for the pole to pole tunnel. See for example, R. H. Romer, The answer is forty-two – many mechanics problems, only one answer, *Physics Teacher* **41**, pp. 286–290, May 2003.

Challenge 339, page 176: There is no simple answer: the speed depends on the latitude and on other parameters.

Challenge 340, page 176: The centrifugal force must be equal to the gravitational force. Call the constant linear mass density d and the unknown length l. Then we have $GMd\int_R^{R+l} \mathrm{d}r/r^2 = \omega^2 d\int_R^{R+l} r\,\mathrm{d}r$. This gives $GMdl/(R^2 + Rl) = (2Rl + l^2)\omega^2 d/2$, yielding $l = 0.14\,\text{Gm}$.

Challenge 342, page 176: The inner rings must rotate faster than the outer rings. If the rings were solid, they would be torn apart. But this reasoning is true only if the rings are inside a certain limit, the so-called *Roche limit*. The Roche limit is that radius at which gravitational force F_g and tidal force F_t cancel on the surface of the satellite. For a satellite with mass m and radius r, orbiting a central mass M at distance d, we look at the forces on a small mass μ on its surface. We get the condition $Gm\mu/r^2 = 2GM\mu r/d^3$. With a bit of algebra, one gets the Roche limit

$$d_\text{Roche} = R(2\frac{\rho_M}{\rho_m})^{1/3} \,. \tag{126}$$

Below that distance from a central mass M, fluid satellites cannot exist. The calculation shown here is only an approximation; the actual Roche limit is about two times that value.

Challenge 347, page 180: In reality muscles keep an object above ground by continuously lifting and dropping it; that requires energy and work.

Challenge 348, page 180: The electricity consumption of a rising escalator indeed increases when the person on it walks upwards. By how much?

Challenge 349, page 180: Knowledge is power. Time is money. Now, power is defined as work per time. Inserting the previous equations and transforming them yields

$$\text{money} = \frac{\text{work}}{\text{knowledge}} \,, \tag{127}$$

which shows that the less you know, the more money you make. That is why scientists have low salaries.

Challenge 351, page 181: The lack of static friction would avoid that the fluid stays attached to the body; the so-called boundary layer would not exist. One then would have to wing effect.

Challenge 353, page 183: True?

Challenge 355, page 184: From $\mathrm{d}v/\mathrm{d}t = g - v^2(1/2c_w A\rho/m)$ and using the abbreviation $c = 1/2c_w A\rho$, we can solve for $v(t)$ by putting all terms containing the variable v on one side, all terms with t on the other, and integrating on both sides. We get $v(t) = \sqrt{gm/c}\tanh\sqrt{cg/m}\,t$.

Challenge 357, page 186: The phase space has $3N$ position coordinates and $3N$ momentum coordinates.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

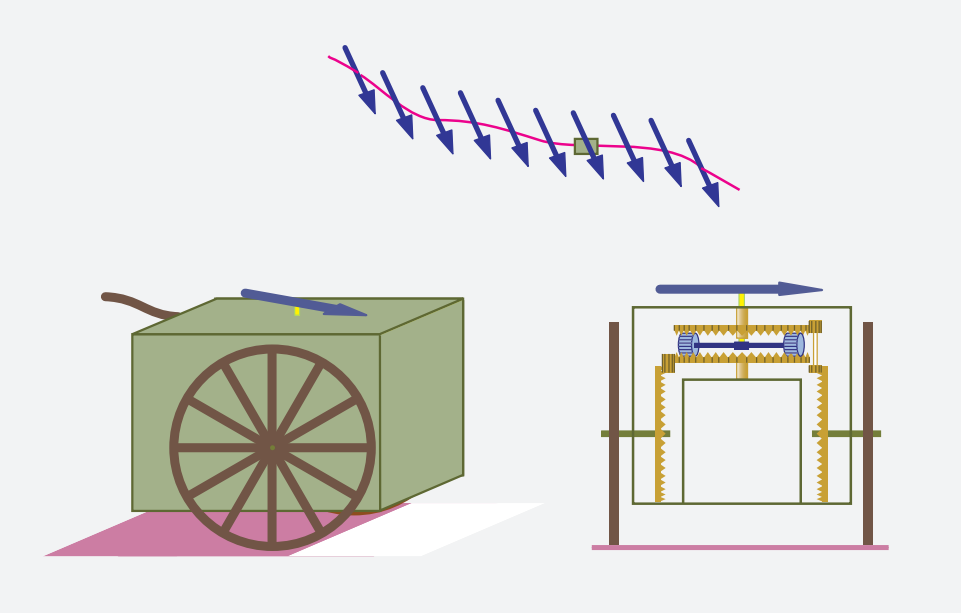

FIGURE 222 The mechanism inside the south-pointing carriage

Page 745 **Challenge 358**, page 186: The light mill is an example.

Challenge 359, page 186: Electric charge.

Challenge 360, page 186: If you have found reasons to answer yes, you overlooked something. Just go into more details and check whether the concepts you used apply to the universe. Also define carefully what you mean by 'universe'.

Challenge 362, page 187: A system showing energy or matter motion faster than light would imply that for such systems there are observers for which the order between cause and effect are reversed. A space-time diagram (and a bit of exercise from the section on special relativity) shows this.

Challenge 363, page 188: If reproducibility would not exist, we would have difficulties in checking observations; also reading the clock is an observation. The connection between reproducibility and time shall become important in the final part of our adventure.

Challenge 364, page 189: Even if surprises were only rare, each surprise would make it impossible to define time just before and just after it.

Challenge 367, page 189: Of course; moral laws are summaries of what others think or will do about personal actions.

Challenge 368, page 190: The fastest glide path between two points, the *brachistochrone*, turns out to be the *cycloid*, the curve generated by a point on a wheel that is rolling along a horizontal plane.

The proof can be found in many ways. The simplest is...

Challenge 371, page 191: Figure 222 shows the most credible reconstruction of a south-pointing carriage.

Challenge 372, page 192: The water is drawn up along the sides of the spinning egg. The fastest way to empty a bottle of water is to spin the water while emptying it.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 373, page 192: The right way is the one where the chimney falls like a V, not like an inverted V. See challenge 295 on falling brooms for inspiration on how to deduce the answer. It turns out that the chimney breaks (if it is not fastened to the base) at a height between half or two thirds of the total, depending at the angle at which this happens. For a complete solution of the problem, see the excellent paper G. VARESCHI & K. KAMIYA, Toy models for the falling chimney, *AMerican Journal of Physics* 71, pp. 1025–1031, 2003.

Challenge 381, page 200: In one dimension, the expression $F = ma$ can be written as $-\mathrm{d}V/\mathrm{d}x = m\mathrm{d}^2x/\mathrm{d}t^2$. This can be rewritten as $\mathrm{d}(-V)/\mathrm{d}x - \mathrm{d}/\mathrm{d}t[\mathrm{d}/\mathrm{d}\dot{x}(\frac{1}{2}m\dot{x}^2)] = 0$. This can be expanded to $\partial/\partial x(\frac{1}{2}m\dot{x}^2 - V(x)) - \mathrm{d}/[\partial/\partial\dot{x}(\frac{1}{2}m\dot{x}^2 - V(x))] = 0$, which is Lagrange's equation for this case.

Challenge 383, page 200: Do not despair. Up to now, nobody has been able to imagine a universe (that is not necessarily the same as a 'world') different from the one we know. So far, such attempts have always led to logical inconsistencies.

Challenge 385, page 202: The two are equivalent since the equations of motion follow from the principle of minimum action and at the same time the principle of minimum action follows from the equations of motion.

Challenge 387, page 203: For gravity, all three systems exist: rotation in galaxies, pressure in planets and the Pauli pressure in stars. Against the strong interaction, the Pauli principle acts in nuclei and neutron stars; in neutron stars maybe also rotation and pressure complement the Pauli pressure. But for the electromagnetic interaction there are no composites other than our everyday matter, which is organized by the Pauli principle alone.

Challenge 389, page 206: Angular momentum is the change with respect to angle, whereas rotational energy is again the change with respect to time, as all energy is.

Challenge 390, page 206: Not in this way. A small change can have a large effect, as every switch shows. But a small change in the brain must be communicated outside, and that will happen roughly with a $1/r^2$ dependence. That makes the effects so small, that even with the most sensitive switches – which for thoughts do not exist anyway – no effects can be realized.

Challenge 393, page 207: The relation is

$$\frac{c_1}{c_2} = \frac{\sin\alpha_1}{\alpha_2} \,. \tag{128}$$

The particular speed ratio between air (or vacuum, which is almost the same) and a material gives the *index of refraction n*:

$$n = \frac{c_1}{c_0} = \frac{\sin\alpha_1}{\alpha_0} \tag{129}$$

Challenge 394, page 207: Gases are mainly made of vacuum. Their index of refraction is near to one.

Challenge 395, page 207: Diamonds also sparkle because they work as prisms; different colours have different indices of refraction. Thus their sparkle is also due to their dispersion; therefore it is a mix of all colours of the rainbow.

Challenge 396, page 207: The principle for the growth of trees is simply the minimum of potential energy, since the kinetic energy is negligible. The growth of vessels inside animal bodies is minimized for transport energy; that is again a minimum principle. The refraction of light is the path of shortest time; thus it minimizes change as well, if we imagine light as moving entities moving without any potential energy involved.

Challenge 397, page 207: Special relativity requires that an invariant measure of the action exist. It is presented later in the walk.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 398, page 207: The universe is not a physical system. This issue will be discussed in detail later on.

Page 1440

Challenge 399, page 208: Use either the substitution $u = \tan t/2$ or use the historical trick

$$\sec\varphi = \frac{1}{2}\left(\frac{\cos\varphi}{1+\sin\varphi} + \frac{\cos\varphi}{1+\sin\varphi}\right) . \tag{130}$$

Challenge 400, page 209: We talk to a person because we know that somebody understands us. Thus we assume that she somehow sees the same things we do. That means that observation is partly viewpoint-independent. Thus nature is symmetric.

Challenge 401, page 211: Memory works because we recognize situations. This is possible because situations over time are similar. Memory would not have evolved without this reproducibility.

Challenge 402, page 212: Taste differences are not fundamental, but due to different viewpoints and – mainly – to different experiences of the observers. The same holds for feelings and judgements, as every psychologist will confirm.

Challenge 403, page 213: The integers under addition form a group. Does a painter's set of oil colours with the operation of mixing form a group?

Challenge 404, page 213: There is only one symmetry operation: a rotation about π around the central point. That is the reason that later on the group D_4 is only called approximate symmetry group.

Challenge 410, page 217: Scalar is the magnitude of any vector; thus the speed, defined as $v = |\boldsymbol{v}|$, is a scalar, whereas the velocity $\boldsymbol{v}$ is not. Thus the length of any vector (or pseudovector), such as force, acceleration, magnetic field, or electric field, is a scalar, whereas the vector itself is not a scalar.

Challenge 413, page 218: The charge distribution of an extended body can be seen as a sum of a charge, a charge dipole, a charge quadrupole, a charge octupole, etc. The quadrupole is described by a tensor.

Compare: The inertia against motion of an extended body can be seen as sum of a mass, a mass dipole, a mass quadrupole, a mass octupole, etc. The mass quadrupole is described by the moment of inertia.

Challenge 417, page 220: The conserved charge for rotation invariance is angular momentum.

Challenge 420, page 223: An oscillation has a period in time, i.e., a discrete time translation symmetry. A wave has both discrete time and discrete space translation symmetry.

Challenge 421, page 223: Motion reversal is a symmetry for any closed system; despite the observations of daily life, the statements of thermodynamics and the opinion of several famous physicists (who form a minority though) all ideally closed systems are reversible.

Challenge 432, page 231: The potential energy is due to the 'bending' of the medium; a simple displacement produces no bending and thus contains no energy. Only the gradient captures the bending idea.

Challenge 434, page 232: The phase changes by π.

Challenge 436, page 233: Waves can be damped to extremely low intensities. If this is not possible, the observation is not a wave.

Challenge 437, page 234: The way to observe diffraction and interference with your naked fingers is told on page 726.

Challenge 444, page 243: If the distances to the loudspeaker is a few metres, and the distance to the orchestra is 20 m, as for people with enough money, the listener at home hears it first.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 446, page 243: An ellipse (as for planets around the Sun) with the fixed point as centre (in contrast to planets, where the Sun is in a focus of the ellipse).

Challenge 449, page 244: The sound of thunder or of car traffic gets lower and lower in frequency with increasing distance.

Challenge 451, page 244: Neither; both possibilities are against the properties of water: in surface waves, the water molecules move in circles.

Challenge 452, page 244: Swimmers are able to cover 100 m in 48 s, or slightly better than 2 m/s. With a body length of about 1.9 m, the critical speed is 1.7 m/s. That is why short distance swimming depends on training; for longer distances the technique plays a larger role, as the critical speed has not been attained yet. The formula also predicts that on the 1500 m distance, a 2 m tall swimmer has a potential advantage of over 45 s on one with body height of 1.8 m. In addition, longer swimmers have an additional advantage: they swim shorter distances (why?). It is thus predicted that successful long-distance swimmers will get taller and taller over time. This is a pity for a sport that so far could claim to have had champions of all sizes and body shapes, in contrast to many other sports.

Challenge 454, page 246: To reduce noise reflection and thus hall effects. They effectively diffuse the arriving wave fronts.

Challenge 456, page 246: Waves in a river are never elliptical; they remain circular.

Challenge 457, page 246: The lens is a cushion of material that is 'transparent' to sound. The speed of sound is faster in the cushion than in the air, in contrast to a glass lens, where the speed of light is slower in the glass. The shape is thus different: the cushion must look like a biconcave lens.

Challenge 459, page 246: The Sun is always at a different position than the one we observe it to be. What is the difference, measured in angular diameters of the Sun?

Challenge 460, page 246: The $3 \times 3 \times 3$ cube has a rigid system of three perpendicular axes, on which a square can rotate at each of the 6 ends. The other squares are attaches to pieces moving around theses axes. The $4 \times 4 \times 4$ cube is different though; just find out. The limit on the segment number seems to be 6, so far. A $7 \times 7 \times 7$ cube requires varying shapes for the segments. But more than $5 \times 5 \times 5$ is not found in shops. However, the website www.oinkleburger.com/Cube/applet allows to play with virtual cubes up to $100 \times 100 \times 100$ and more.

Challenge 462, page 247: An overview of systems being tested at present can be found in K.-U. Graw, Energiereservoir Ozean, *Physik in unserer Zeit* **33**, pp. 82–88, Februar 2002. See also Oceans of electricity – new technologies convert the motion of waves into watts, *Science News* **159**, pp. 234–236, April 2001.

Challenge 463, page 247: In everyday life, the assumption is usually justified, since each spot can be approximately represented by an atom, and atoms can be followed. The assumption is questionable in situations such as turbulence, where not all spots can be assigned to atoms, and most of all, in the case of motion of the vacuum itself. In other words, for gravity waves, and in particular for the quantum theory of gravity waves, the assumption is not justified.

Challenge 466, page 250: There are many. One would be that the transmission and thus reflection coefficient for waves would almost be independent of wavelength.

Challenge 467, page 251: A drop with a diameter of 3 mm would cover a surface of 7.1 m^2 with a 2 nm film.

Challenge 469, page 255: The critical height for a column of material is given by $h_{\text{crit}}^4 = \frac{\beta}{4\pi g} m \frac{E}{\rho^2}$, where $\beta \approx 1.9$ is the constant determined by the calculation when a column buckles under its own weight.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 472, page 258: One possibility is to describe see particles as extended objects, such as clouds; another is given in the last part of the text.

Challenge 474, page 262: The constant k follows from the conservation of energy and that of mass: $k = \sqrt{2/(\rho(A_1^2/A_2^2 - 1))}$. The cross sections are denoted by A and the subscript 1 refers to any point far from the constriction, and the subscript 2 to the constriction.

Challenge 475, page 264: Some people notice that in some cases friction is too high, and start sucking at one end of the tube to get the flow started; while doing so, they can inhale or swallow gasoline, which is poisonous.

Challenge 481, page 265: The blood pressure in the feet of a standing human is about 27 kPa, double the pressure at the heart.

Challenge 482, page 265: Calculation gives $N = J/j = 0.0001\,\mathrm{m^3/s}/(7\,\mu\mathrm{m}^2 0.0005\,\mathrm{m/s})$, or about $6 \cdot 10^9$; in reality, the number is much larger, as most capillaries are closed at a given instant. The reddening of the face shows what happens when all small blood vessels are opened at the same time.

Challenge 483, page 265: Throwing the stone makes the level fall, throwing the water or the piece of wood leaves it unchanged.

Challenge 484, page 265: The ship rises higher into the sky. (Why?)

Challenge 488, page 265: The pumps worked in suction; but air pressure only allows 10 m of height difference for such systems.

Challenge 489, page 266: This argument is comprehensible only when one remembers that 'twice the amount' means 'twice as many molecules'.

Challenge 490, page 266: The alcohol is frozen and the chocolate is put around it.

Challenge 491, page 266: The author suggested in an old edition that a machine should be based on the same machines that throw the clay pigeons used in the sports of trap shooting and skeet. In the meantime, Lydéric Bocquet and Christophe Clanet have built such a machine, but using a different design; a picture can be found on the website lpmcn.univ-lyon1.fr/%7Elbocquet.

Challenge 492, page 266: The third component of *air* is the noble gas argon, making up about 1 %. The rest is made up by carbon dioxide, water vapour and other gases. Are these percentages volume or weight percentages?

Challenge 493, page 266: The pleural cavity between the lungs and the thorax is permanently below atmospheric pressure. A hole in it, formed for example by a bullet, a sword or an accident, leads to the collapse of the lung – the so-called *pneumothorax* – and often to death. Open chest operations on people have became possible only after the surgeon Ferdinand Sauerbruch learned in 1904 how to cope with the problem. Nowadays, surgeons keep the lung under higher than atmospheric pressure until everything is sealed again.

Challenge 494, page 266: It uses the air pressure created by the water flowing downwards.

Challenge 495, page 266: Yes. The bulb will not resist two such cars though.

Challenge 496, page 266: Radon is about 8 times as heavy as air; it is he densest gas known. In comparison, $Ni(CO)$ is 6 times, $SiCl_4$ 4 times heavier than air. Mercury vapour (obviously also a gas) is 7 times heavier than air. In comparison, bromine vapour is 5.5 times heavier than air.

Challenge 498, page 267: None.

Challenge 500, page 267: He brought the ropes into the cabin by passing them through liquid mercury.

Challenge 501, page 268: The pressure destroys the lung.

Challenge 503, page 268: There are no official solutions for these questions; just check your assumptions and calculations carefully. The internet is full of such calculations.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 504, page 268: The soap flows down the bulb, making it thicker at the bottom and thinner at the top, until it bursts.

Challenge 506, page 268: For this to happen, friction would have to exist on the microscopic scale and energy would have to disappear.

Challenge 507, page 268: The longer funnel is empty before the short one. (If you do not believe it, try it out.) In the case that the amount of water in the funnel outlet can be neglected, one can use energy conservation for the fluid motion. This yields the famous Bernoulli equation $p/\rho + gh + v^2/2 = \text{const}$, where p is pressure, ρ the density of water, and g is $9.81\,\text{m/s}^2$. Therefore, the speed v is higher for greater lengths h of the thin, straight part of the funnel: the longer funnel empties first.

But this is strange: the formula gives a simple free fall relation, as the *air* pressure is the same above and below and disappears from the calculation. The expression for the speed is thus independent of whether a tube is present or not. The real reason for the faster emptying of the tube is thus that a tube forces more water to flow out than the lack of a tube. Without tube, the diameter of the water flow *diminishes* during fall. With tube, it stays *constant*. This difference leads to the faster emptying for longer tubes.

Alternatively, you can look at the *water* pressure value *inside* the funnel. You will discover that the water pressure is lowest at the start of the exit tube. This internal water pressure is lower for longer tubes and sucks out the water faster in those cases.

Challenge 508, page 269: The eyes of fish are positioned in such a way that the pressure reduction by the flow is compensated by the pressure increase of the stall. By the way, their heart is positioned in such a way that it is helped by the underpressure.

Challenge 510, page 269: This feat has been achieved for lower mountains, such as the Monte Bianco in the Alps. At present however, there is no way to safely hover at the high altitudes of the Himalayas.

Challenge 512, page 269: Press the handkerchief in the glass, and lower the glass into the water with the opening first, while keeping the opening horizontal. This method is also used to lower people below the sea. The paper ball in the bottle will fly towards you. Blowing into a funnel will keep the ping-pong ball tightly into place, and the more so the stronger you blow. Blowing through a funnel towards a candle will make it lean towards you.

Challenge 517, page 271: Glass shatters, glass is elastic, glass shows transverse sound waves, glass does not flow (in contrast to what many books state), not even on scale of centuries, glass molecules are fixed in space, glass is crystalline at small distances, a glass pane supported at the ends does not hang through.

Challenge 518, page 271: No metal wire allows to build such a long wire. Only the idea of carbon nanotubes has raised the hope again; some dream of wire material based on them, stronger than any material known so far. However, no such material is known yet. The system faces many dangers, such as fabrication defects, lightning, storms, meteorites and space debris. All would lead to the breaking of the wires – if such wires will ever exist. But the biggest of all dangers is the lack of cash to build it.

Challenge 520, page 272: A medium-large earthquake would be generated.

Challenge 521, page 272: A stalactite contains a thin channel along its axis through which the water flows, whereas a stalagmite is massive throughout.

Challenge 522, page 272: About 1 part in a thousand.

Challenge 523, page 272: Even though the iron core of the Earth formed by collecting the iron from colliding asteroids which then sunk into the centre of the Earth, the scheme will not work today: in its youth, the Earth was much more liquid than today. The iron will most probably not

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

sink. In addition, there is no known way to build a measurement probe that can send strong enough sound waves for this scheme. The temperature resistance is also an issue, but this may be solvable.

Challenge 525, page 274: Atoms are not infinitely hard, as quantum theory shows. Atoms are more similar to deformable clouds.

Page 1022

Challenge 527, page 281: In 5000 million years, the present method will stop, and the Sun will become a red giant. But it will burn for many more years after that.

Challenge 531, page 285: We will find out later that the universe is not a physical system; thus the concept of entropy does not apply to it. Thus the universe is neither isolated nor closed.

Page 1440

Challenge 534, page 286: The answer depends on the size of the balloons, as the pressure is not a monotonous function of the size. If the smaller balloon is not too small, the smaller balloon wins.

Challenge 536, page 286: Measure the area of contact between tires and street (all four) and then multiply by 200 kPa, the usual tire pressure. You get the weight of the car.

Challenge 541, page 288: If the average square displacement is proportional to time, the matter is made of smallest particles. This was confirmed by the experiments of Jean Perrin. The next step is to deduce the number of these particles form the proportionality constant. This constant, defined by $\langle d^2 \rangle = 4Dt$, is called the diffusion constant (the factor 4 is valid for random motion in two dimensions). The diffusion constant can be determined by watching the motion of a particle under the microscope.

We study a Brownian particle of radius a. In two dimensions, its square displacement is given by

$$\langle d^2 \rangle \frac{4kT}{\mu} t \,, \tag{131}$$

where k is the Boltzmann constant and T the temperature. The relation is deduced by studying the motion of a particle with drag force $-\mu v$ that is subject to random hits. The linear drag coefficient μ of a sphere of radius a is given by

$$\mu = 6\pi\eta a \,. \tag{132}$$

In other words, one has

$$k = \frac{6\pi\eta a}{4T} \frac{\langle d^2 \rangle}{t} \,. \tag{133}$$

All quantities on the right can be measured, thus allowing to determine the Boltzmann constant k. Since the ideal gas relation shows that the ideal gas constant R is related to the Boltzmann constant by $R = N_A k$, the Avogadro constant N_A that gives the number of molecules in a mole is also found in this way.

Challenge 549, page 295: Yes, the effect is easily noticeable.

Challenge 551, page 295: Hot air is less dense and thus wants to rise.

Challenge 552, page 295: Keep the paper wet.

Challenge 554, page 296: The air had to be dry.

Challenge 555, page 296: In general, it is impossible to draw a line through three points. Since absolute zero and the triple point of water are fixed in magnitude, it was practically a sure bet that the boiling point would not be at precisely 100 °C.

Challenge 556, page 296: No, as a water molecule is heavier than that. However, if the water is allowed to be dirty, it is possible. What happens if the quantum of action is taken into account?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

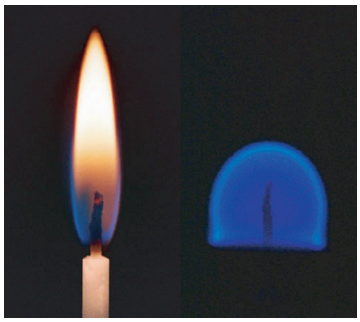

FIGURE 223 A candle on Earth and in microgravity (NASA)

Challenge 557, page 296: The danger is not due to the amount of energy, but due to the time in which it is available.

Challenge 558, page 297: The internet is full of solutions.

Challenge 560, page 297: Only if it is a closed system. Is the universe closed? Is it a system? This is discussed in the final part of the mountain ascent.

Challenge 563, page 298: For such small animals the body temperature would fall too low. They could not eat fast enough to get the energy needed to keep themselves warm.

Challenge 572, page 299: It is about 10^{-9} that of the Earth.

Challenge 574, page 299: The thickness of the folds in the brain, the bubbles in the lung, the density of blood vessels and the size of biological cells.

Challenge 575, page 299: The mercury vapour above the liquid gets saturated.

Challenge 576, page 299: A dedicated NASA project studied this question. Figure 223 gives an example comparison. You can find more details on their website.

Challenge 577, page 299: The risks due to storms and the financial risks are too large.

Challenge 578, page 300: The vortex inside the tube is cold near its axis and hot in the regions away from the axis. Through the membrane in the middle of the tube (shown in Figure 194 on page 300) the air from the axis region is sent to one end and the air from the outside region to the other end. The heating of the outside region is due to the work that the air rotating inside has to do on the air outside to get a rotation that consumes angular momentum. For a detailed explanation, see the beautiful text by MARK P. SILVERMAN, *And Yet it Moves: Strange Systems and Subtle Questions in Physics*, Cambridge University Press, 1993, p. 221.

Challenge 579, page 300: Egg white hardens at 70°C, egg yolk at 65 to 68°C. Cook an egg at the latter temperature, and the feat is possible.

Challenge 583, page 300: In the case of water, a few turns mixes the ink, and turning backwards increases the mixing. In the case of glycerine, a few turns *seems* to mix the ink, and turning backwards undoes the mixing.

Challenge 585, page 301: Negative temperatures are a conceptual crutch definable only for systems with a few discrete states; they are not real temperatures, because they do not describe equilibrium states, and indeed never apply to systems with a continuum of states.

Challenge 586, page 302: This is also true for the shape human bodies, the brain control of human motion, the growth of flowers, the waves of the sea, the formation of clouds, the processes leading to volcano eruptions, etc.

Challenge 591, page 308: First, there are many more butterflies than tornadoes. Second, tornadoes do not rely on small initial disturbances for their appearance. Third, the belief in the butter-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

fly 'effect' completely neglects an aspect of nature that is essential for self-organization: friction and dissipation. The butterfly 'effect', assumed that it existed, would require that dissipation in the air should have completely unrealistic properties. This is not the case in the atmosphere. But most important of all, there is no experimental basis for the 'effect': it has never been observed. Thus it does not exist.

Challenge 602, page 315: All three statements are hogwash. A drag coefficient implies that the cross area of the car is known to the same precision. This is actually extremely difficult to measure and to keep constant. In fact, the value 0.375 for the Ford Escort was a cheat, as many other measurements showed. The fuel consumption is even more ridiculous, as it implies that fuel volumes and distances can be measured to that same precision. Opinion polls are taken by phoning at most 2000 people; due to the difficulties in selecting the right representative sample, that gives a precision of at most 3 %.

Challenge 603, page 316: No. Nature does not allow more than about 20 digits of precision, as we will discover later in our walk. That is not sufficient for a standard book. The question whether such a number can be part of its own book thus disappears.

Challenge 605, page 317: Space-time is defined using matter; matter is defined using space-time.

Challenge 606, page 317: Fact is that physics has been based on a circular definition for hundreds of years. Thus it is possible to build even an exact science on sand. Nevertheless, the elimination of the circularity is an important aim.

Challenge 607, page 317: Every measurement is a comparison with a standard; every comparison requires light or some other electromagnetic field. This is also the case for time measurements.

Challenge 608, page 317: Every mass measurement is a comparison with a standard; every comparison requires light or some other electromagnetic field.

Challenge 609, page 317: Angle measurements have the same properties as length or time measurements.

Challenge 611, page 333: For example, speed inside materials is slowed, but between atoms, light still travels with vacuum speed.

CREDITS

Acknowledgements

Many people who have kept their gift of curiosity alive have helped to make this project come true. Most of all, Saverio Pascazio has been – present or not – a constant reference for this project. Fernand Mayné, Anna Koolen, Ata Masafumi, Roberto Crespi, Serge Pahaut, Luca Bombelli, Herman Elswijk, Marcel Krijn, Marc de Jong, Martin van der Mark, Kim Jalink, my parents Peter and Isabella Schiller, Mike van Wijk, Renate Georgi, Paul Tegelaar, Barbara and Edgar Augel, M. Jamil, Ron Murdock, Carol Pritchard, Richard Hoffman, Stephan Schiller and, most of all, my wife Britta have all provided valuable advice and encouragement.

Many people have helped with the project and the collection of material. Most useful was the help of Mikael Johansson, Bruno Barberi Gnecco, Lothar Beyer, the numerous improvements by Bert Sierra, the detailed suggestions by Claudio Farinati, the many improvements by Eric Sheldon, the detailed suggestions by Andrew Young, the continuous help and advice of Jonatan Kelu, the corrections of Elmar Bartel, and in particular the extensive, passionate and conscientious help of Adrian Kubala.

Important material was provided by Bert Peeters, Anna Wierzbicka, William Beaty, Jim Carr, John Merrit, John Baez, Frank DiFilippo, Jonathan Scott, Jon Thaler, Luca Bombelli, Douglas Singleton, George McQuarry, Tilman Hausherr, Brian Oberquell, Peer Zalm, Martin van der Mark, Vladimir Surdin, Julia Simon, Antonio Fermani, Don Page, Stephen Haley, Peter Mayr, Allan Hayes, Norbert Dragon, Igor Ivanov, Doug Renselle, Wim de Muynck, Steve Carlip, Tom Bruce, Ryan Budney, Gary Ruben, Chris Hillman, Olivier Glassey, Jochen Greiner, squark, Martin Hardcastle, Mark Biggar, Pavel Kuzin, Douglas Brebner, Luciano Lombardi, Franco Bagnoli, Lukas Fabian Moser, Dejan Corovic, Steve Carlip, Corrado Massa, Tom Helmond, Gary Gibbons, Heinrich Neumaier, Peter Brown, Paul Vannoni, John Haber, Saverio Pascazio, Klaus Finkenzeller, Leo Volin, Jeff Aronson, Roggie Boone, Lawrence Tuppen, Quentin David Jones, Arnaldo Uguzzoni, Frans van Nieuwpoort, Alan Mahoney, Britta Schiller, Petr Danecek, Ingo Thies, Vitaliy Solomatin, Carl Offner, Nuno Proença, Elena Colazingari, Paula Henderson, Daniel Darre, Wolfgang Rankl, John Heumann, Joseph Kiss, Martha Weiss, Antonio González, Antonio Martos, André Slabber, Ferdinand Bautista, Zoltán Gácsi, Pat Furrie, Michael Reppisch, Enrico Pasi, Thomas Köppe, Martin Rivas, Herman Beeksma, Tom Helmond, John Brandes, Vlad Tarko, Nadia Murillo, Ciprian Dobra, Romano Perini, Harald van Lintel, Andrea Conti, François Belfort, Dirk Van de Moortel, Heinrich Neumaier, Jarosław Królikowski, John Dahlman, Fathi Namouni, Paul Townsend, Sergei Emelin, Freeman Dyson, S.R. Madhu Rao, David Parks, Jürgen Janek, Daniel Huber, Alfons Buchmann, William Purves, Pietro Redondi, Sergei Kopeikin, plus a number of people who wanted to remain unnamed.

The software tools were refined with extensive help on fonts and typesetting by Michael Zedler and Achim Blumensath and with the repeated and valuable support of Donald Arseneau; help came also from Ulrike Fischer, Piet van Oostrum, Gerben Wierda, Klaus Böhncke, Craig Upright, Herbert Voss, Andrew Trevorrow, Danie Els, Heiko Oberdiek, Sebastian Rahtz, Don Story, Vin-

cent Darley, Johan Linde, Joseph Hertzlinger, Rick Zaccone, John Warkentin, Ulrich Diez, Uwe Siart, Will Robertson, Joseph Wright Enrico Gregorio, Rolf Niepraschk and Alexander Grahn.

All illustrations and animations in the text were made available by the copyright holders. A warm thank you to all of them. They are mentioned in the image and film credit sections. In particular, Luca Gastaldi, Antonio Martos and Ulrich Kolberg produced images specifically for this text; Lucas Barbosa and José Antonio Díaz Navas produced special animations. The typesetting and book design is due to the professional consulting of Ulrich Dirr. The design of the book and its website owe also much to the suggestions and support of my wife Britta.

Since May 2007, the production and distribution of this text is generously supported by the Klaus Tschira Foundation.

Film credits

The clear animation of a suspended spinning top, shown on page 125, was made for this text by Lucas V. Barbosa. The beautiful animation of the lunation on page 153 was calculated from actual astronomical data and is copyright and courtesy by Martin Elsässer. It can be found on his website www.mondatlas.de/lunation.html. The film of an oscillating quartz on page 228 is copyright and courtesy of Micro Crystal, part of the Swatch Group, found at www.microcrystal.com. The films of solitons on page 242 and of dromions on page 249 are copyright and courtesy by Jarmo Hietarinta. They can be found on his website users.utu.fi/hietarin. The film of leapfrogging vortex rings on page 271 is copyright and courtesy by Lim Tee Tai. It can be found via his fluid dynamics website serve.me.nus.edu.sg. The film of the growing snowflake on page 306 is copyright and courtesy by Kenneth Libbrecht. It can be found on his website www.its.caltech.edu/~atomic/snowcrystals.

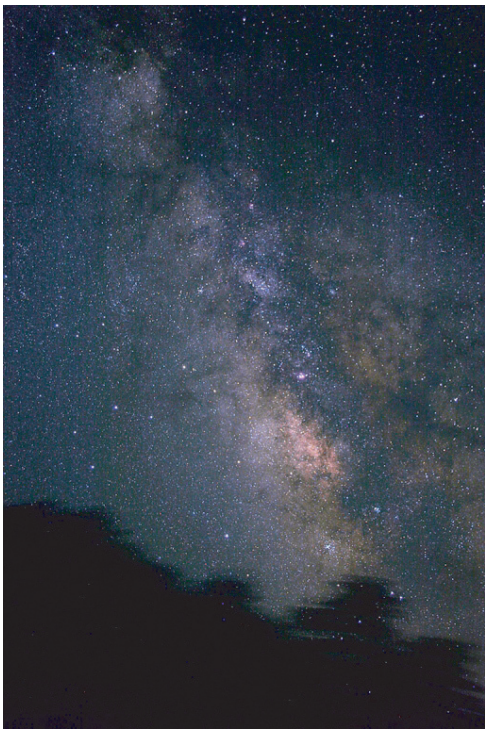
Second Part



Relativity

In our quest to learn how things move,
the experience of hiking and other motion
leads us to discover that there is a maximum speed in nature,
and that two events that happen at the same time for one observer
may not for another.
We discover that empty space can bend, wobble and move,
we find that there is a maximum force in nature,
and we understand why we can see the stars.

Contents

Chapter 15

MAXIMUM SPEED, OBSERVERS AT REST, AND MOTION OF LIGHT

> Fama nihil est celerius.*
>
> Antiquity

Light is indispensable for a precise description of motion. To check whether a line or a path of motion is straight, we must look along it. In other words, we use light to define straightness. How do we decide whether a plane is flat? We look across it,** again using light. How do we measure length to high precision? With light. How do we measure time to high precision? With light: once it was light from the Sun that was used; nowadays it is light from caesium atoms.

Page 909

Light is important because it is the standard for *undisturbed motion*. Physics would have evolved much more rapidly if, at some earlier time, light propagation had been recognized as the ideal example of motion.

But is light really a phenomenon of motion? Yes. This was already known in ancient Greece, from a simple daily phenomenon, the *shadow*. Shadows prove that light is a moving entity, emanating from the light source, and moving in straight lines.*** The Greek thinker Empedocles (*c.* 490 to *c.* 430 BCE) drew the logical conclusion that light takes a certain amount of time to travel from the source to the surface showing the shadow.

Ref. 294

Empedocles stated that the speed of light is finite. We can confirm this result with a different, equally simple, but subtle argument. Speed can be measured. And measurement is comparison with a standard. Therefore the *perfect* speed, which is used as the implicit measurement standard, must have a finite value. An infinite velocity standard would not allow measurements at all. In nature, the lightest entities move with the highest speed.

Challenge 613 s

* 'Nothing is faster than rumour.' This common sentence is a simplified version of Virgil's phrase: *fama, malum qua non aliud velocius ullum.* 'Rumour, the evil faster than all.' From the *Aeneid*, book IV, verses 173 and 174.

** Note that looking along the plane from all sides is not sufficient for this check: a surface that a light beam touches right along its length in *all* directions does not need to be flat. Can you give an example? One needs other methods to check flatness with light. Can you specify one?

Challenge 612 s

*** Whenever a source produces shadows, the emitted entities are called *rays* or *radiation*. Apart from light, other examples of radiation discovered through shadows were *infrared rays* and *ultraviolet rays*, which emanate from most light sources together with visible light, and *cathode rays*, which were found to be to the motion of a new particle, the *electron*. Shadows also led to the discovery of *X-rays*, which again turned out to be a version of light, with high frequency. *Channel rays* were also discovered via their shadows; they turn out to be travelling ionized atoms. The three types of radioactivity, namely *α-rays* (helium nuclei), *β-rays* (again electrons), and *γ-rays* (high-energy X-rays) also produce shadows. All these discoveries were made between 1890 and 1910: those were the 'ray days' of physics.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

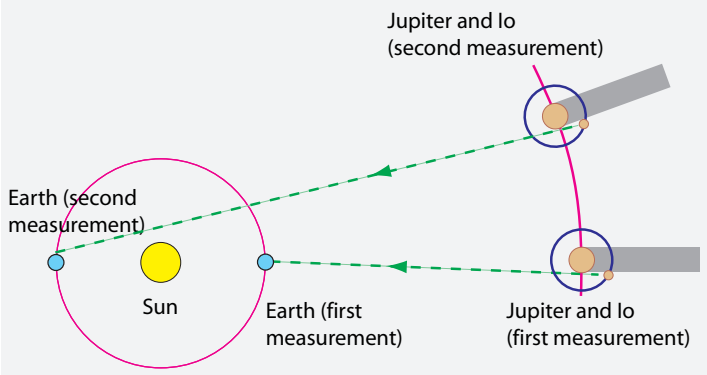

FIGURE 224 Rømer's method of measuring the speed of light

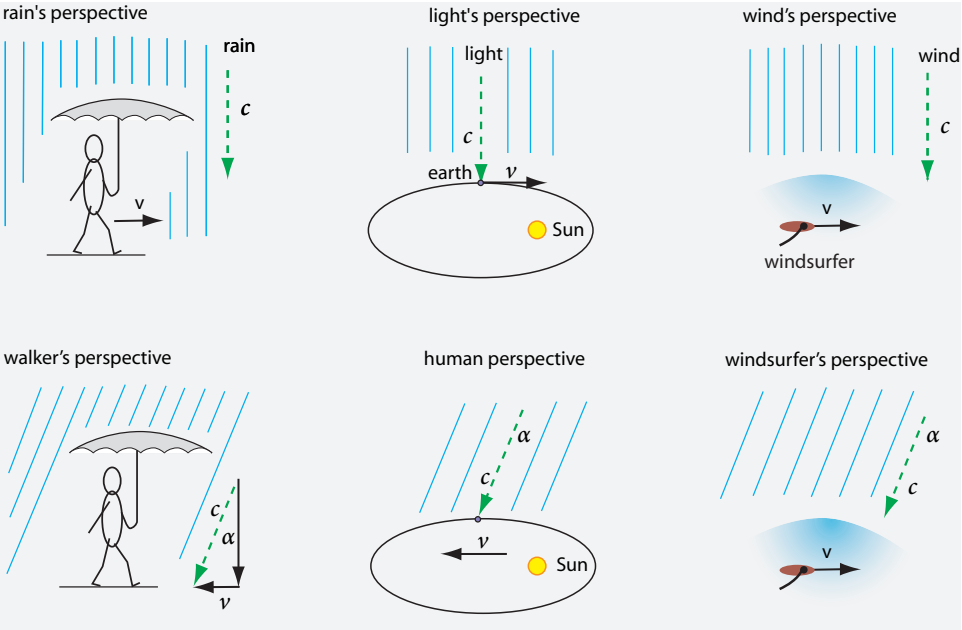

FIGURE 225 The rainwalker's or windsurfer's method of measuring the speed of light

Light, which is indeed extremely light, is an obvious candidate for motion with perfect but finite speed. We will confirm this in a minute.

A finite speed of light means that whatever we see is a message from the *past*. When we see the stars,* the Sun or a person we love, we always see an image of the past. In a sense, nature prevents us from enjoying the present – we must therefore learn to enjoy the past.

The speed of light is high; therefore it was not measured until the years 1668 to 1676, even though many, including Galileo, had tried to do so earlier. The first measurement

* The photograph of the night sky and the milky way, on page 397 is copyright Anthony Ayiomamitis and is found on his splendid website www.perseus.gr.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 295 Page 168 method was worked out and published by the Danish astronomer Ole Rømer* when he was studying the orbits of Io and the other Galilean satellites of Jupiter. He did not obtain any specific value for the speed of light because he had no reliable value for the satellite's distance from Earth and because his timing measurements were unprecise. The Ref. 296 lack of a numerical result was quickly corrected by his peers, mainly Christiaan Huygens Challenge 614 s and Edmund Halley. (You might try to deduce Rømer's method from Figure 224.) Since Rømer's time it has been known that light takes a bit more than 8 minutes to travel from the Sun to the Earth. This result was confirmed in a beautiful way fifty years later, in 1726, Page 128 by the astronomer James Bradley. Being English, Bradley thought of the 'rain method' to Ref. 297 measure the speed of light.

How can we measure the speed of falling rain? We walk rapidly with an umbrella, measure the angle α at which the rain appears to fall, and then measure our own velocity v. (We can clearly see the angle while walking if we look at the rain to our left or right, if possible against a dark background.) As shown in Figure 225, the speed c of the rain is then given by

$$c = v/\tan\alpha \ . \tag{134}$$

In the same way we can measure the speed of wind when on a surfboard or on a ship. The same measurement can be made for light; we just need to measure the angle at which the light from a star above Earth's orbit arrives at the Earth. Because the Earth is moving relative to the Sun and thus to the star, the angle is not 90°. This deviation is called the *aberration* of light; the angle is determined most easily by comparing measurements made six months apart. The value of the aberration angle is 20.5″. (Nowadays it can be measured with a precision of five decimal digits.) Given that the speed of the Earth around the Sun is $v = 2\pi R/T = 29.7\,\mathrm{km/s}$, the speed of light must therefore be $c = 0.300\,\mathrm{Gm/s}$.** This is

* Ole (Olaf) Rømer (1644 Aarhus – 1710 Copenhagen), Danish astronomer. He was the teacher of the Dauphin in Paris, at the time of Louis XIV. The idea of measuring the speed of light in this way was due to the Italian astronomer Giovanni Cassini, whose assistant Rømer had been. Rømer continued his measurements until 1681, when Rømer had to leave France, like all protestants (such as Christiaan Huygens), so that his work was interrupted. Back in Denmark, a fire destroyed all his measurement notes. As a result, he was not able to continue improving the precision of his method. Later he became an important administrator and reformer of the Danish state.

** Umbrellas were not common in Britain in 1726; they became fashionable later, after being introduced from China. The umbrella part of the story is made up. In reality, Bradley had his idea while sailing on the Thames, when he noted that on a moving ship the apparent wind has a different direction from that on land. He had observed 50 stars for many years, notably Gamma Draconis, and during that time he had been puzzled by the *sign* of the aberration, which was *opposite* to the effect he was looking for, namely the star parallax. Both the parallax and the aberration for a star above the ecliptic make them describe a small Challenge 615 s ellipse in the course of an Earth year, though with different rotation senses. Can you see why?

By the way, it follows from special relativity that the formula (134) is wrong, and that the correct formula Challenge 616 s is $c = v/\sin\alpha$; can you see why?

To determine the speed of the Earth, we first have to determine its distance from the Sun. The simplest method is the one by the Greek thinker Aristarchos of Samos (*c.* 310 to *c.* 230 BCE). We measure the angle between the Moon and the Sun at the moment when the Moon is precisely half full. The cosine of that angle gives the ratio between the distance to the Moon (determined, for example, by the methods of page 144) Challenge 617 s and the distance to the Sun. The explanation is left as a puzzle for the reader.

The angle in question is almost a right angle (which would yield an infinite distance), and good instru- Ref. 298 ments are needed to measure it with precision, as Hipparchos noted in an extensive discussion of the prob-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

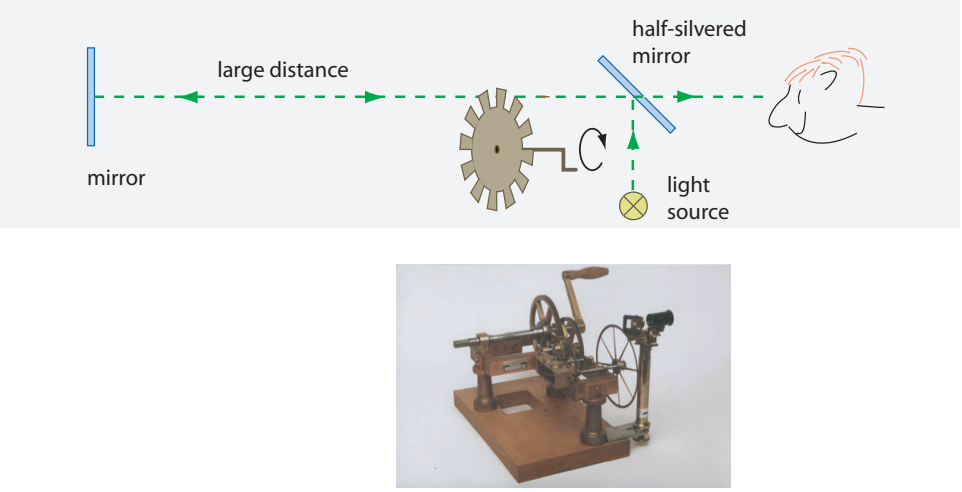

FIGURE 226 Fizeau's set-up to measure the speed of light (photo © AG Didaktik und Geschichte der Physik, Universität Oldenburg)

an astonishing value, especially when compared with the highest speed ever achieved by a man-made object, namely the Voyager satellites, which travel at 52 Mm/h = 14 km/s, with the growth of children, about 3 nm/s, or with the growth of stalagmites in caves, about 0.3 pm/s. We begin to realize why measurement of the speed of light is a science in its own right.

The first *precise* measurement of the speed of light was made in 1849 by the French physicist Hippolyte Fizeau (1819–1896). His value was only 5 % greater than the modern one. He sent a beam of light towards a distant mirror and measured the time the light took to come back. How did Fizeau measure the time without any electric device? In fact, he used the same ideas that are used to measure bullet speeds; part of the answer is given in Figure 226. (How far away does the mirror have to be?) A modern reconstruction of his experiment by Jan Frercks has achieved a precision of 2 %. Today, the experiment is much simpler; in the chapter on electrodynamics we will discover how to measure the speed of light using two standard UNIX or Linux computers connected by a cable.

Page 62
Challenge 619 s
Ref. 300
Page 682

The speed of light is so high that it is even difficult to prove that it is *finite*. Perhaps the most beautiful way to prove this is to photograph a light pulse flying across one's field of view, in the same way as one can photograph a car driving by or a bullet flying through the air. Figure 227 shows the first such photograph, produced in 1971 with a

Ref. 301

lem around 130 BCE. Precise measurement of the angle became possible only in the late seventeenth century, when it was found to be 89.86°, giving a distance ratio of about 400. Today, thanks to radar measurements of planets, the distance to the Sun is known with the incredible precision of 30 metres. Moon distance variations can even be measured to the nearest centimetre; can you guess how this is achieved?

Page 923
Challenge 618 s
Ref. 299

Aristarchos also determined the radius of the Sun and of the Moon as multiples of those of the Earth. Aristarchos was a remarkable thinker: he was the first to propose the heliocentric system, and perhaps the first to propose that stars were other, faraway suns. For these ideas, several of his contemporaries proposed that he should be condemned to death for impiety. When the Polish monk and astronomer Nicolaus Copernicus (1473–1543) again proposed the heliocentric system two thousand years later, he did not mention Aristarchos, even though he got the idea from him.

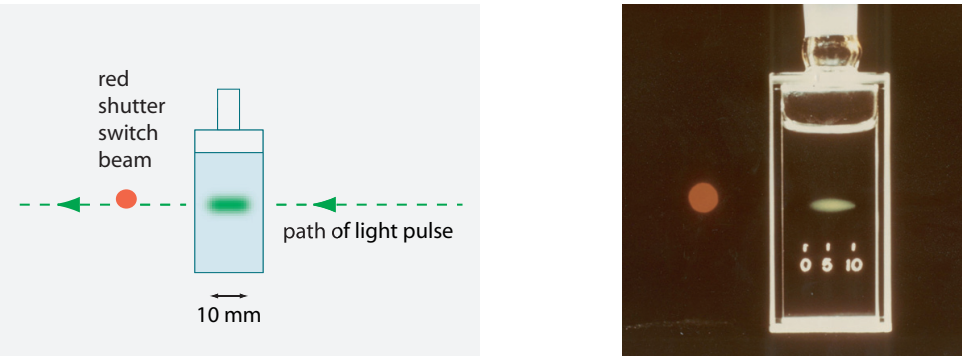

FIGURE 227 A photograph of a light pulse moving from right to left through a bottle with milky water, marked in millimetres (photograph © Tom Mattick)

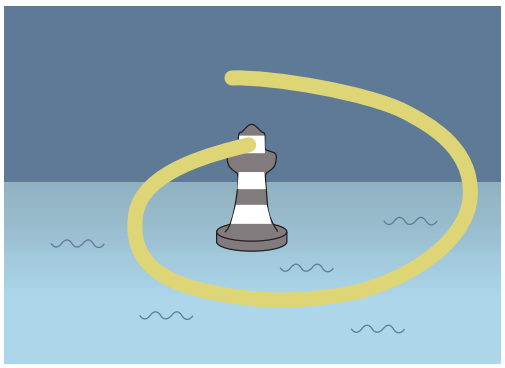

FIGURE 228 A consequence of the finiteness of the speed of light (watch out for the tricky details – light *does* travel straight from the source, it does *not* move along the drawn curved line)

standard off-the-shelf reflex camera, a very fast shutter invented by the photographers, and, most noteworthy, not a single piece of electronic equipment. (How fast does such a shutter have to be? How would you build such a shutter? And how would you make sure it opened at the right instant?) Challenge 620 s

A finite speed of light also implies that a rapidly rotating light beam behaves as shown as in Figure 228. In everyday life, the high speed of light and the slow rotation of lighthouses make the effect barely noticeable.

In short, light moves extremely rapidly. It is much faster than lightning, as you might like to check yourself. A century of increasingly precise measurements of the speed have culminated in the modern value Challenge 621 s

$$c = 299\,792\,458\,\mathrm{m/s}. \tag{135}$$

In fact, this value has now been fixed *exactly*, by definition, and the metre has been defined in terms of c. Table 49 gives a summary of what is known today about the motion of light. Two of the most surprising properties were discovered in the late nineteenth century. They form the basis of special relativity. Ref. 302

TABLE 49 Properties of the motion of light

OBSERVATIONS ABOUT LIGHT
Light can move through vacuum.
Light transports energy.
Light has momentum: it can hit bodies.
Light has angular momentum: it can rotate bodies.
Light moves across other light undisturbed.
Light in vacuum always moves faster than any material body does.
The speed of light, its true signal speed, is the forerunner speed. Page 754
In vacuum, the speed of light is 299 792 458 m/s.
The proper speed of light is infinite. Page 425
Shadows can move without any speed limit.
Light moves in a straight line when far from matter.
High-intensity light is a wave.
Light beams are approximations when the wavelength is neglected.
In matter, both the forerunner speed and the energy speed of light are lower than in vacuum.
In matter, the group velocity of light pulses can be zero, positive, negative or infinite.

CAN ONE PLAY TENNIS USING A LASER PULSE AS THE BALL AND MIRRORS AS RACKETS?

> Et nihil est celerius annis.*
>
> Ovid, *Metamorphoses*.

We all know that in order to throw a stone as far as possible, we run as we throw it; we know instinctively that in that case the stone's speed with respect to the ground is higher than if we do not run. However, to the initial astonishment of everybody, experiments show that light emitted from a moving lamp has the same speed as light emitted from a resting one. Light (in vacuum) is never faster than light; all light beams have the same speed. Many specially designed experiments have confirmed this result to high precision. The speed of light can be measured with a precision of better than 1 m/s; but even for lamp speeds of more than 290 000 000 m/s no differences have been found. (Can you guess what lamps were used?)

Ref. 303

Challenge 622 s

In everyday life, we also know that a stone arrives more rapidly if we run towards it than in the case that we stand still or even run away from it. But astonishingly again, for light no such effect exists! All experiments clearly show that if we run towards a lamp, we measure the same speed of light as in the case that we stand still or even run away from it. Also these experiments have been performed to the highest precision possible.

Ref. 317

All experiments thus show that the velocity of light has the *same value* for all observers, even if they are moving with respect to each other or with respect to the light source. The speed of light is indeed the ideal, perfect measurement standard.**

* 'Nothing is faster than the years.' Book X, verse 520.

** An equivalent alternative term for the speed of light is 'radar speed' or 'radio speed'; we will see below

FIGURE 229 Albert Einstein (1879–1955)

Ref. 306 There is also a second set of experimental evidence for the constancy, or better, the invariance of the speed of light. Every electromagnetic device, such as an electric toothbrush, shows that the speed of light is constant. We will discover that magnetic fields would not result from electric currents, as they do every day in every motor and in every loudspeaker, if the speed of light were not constant. This was actually how the invariance was first deduced, by several researchers. Only after understanding this, did the German–Swiss physicist Albert Einstein show that the invariance of the speed of light is also in agreement with the observed motion of bodies. We will check this agreement in this chapter. The connection between electric toothbrushes and relativity will be explored in the chapters on electrodynamics. (For information about direct influences of relativity on machine design, see the interesting textbook by Van Bladel.)

Page 692

Page 692

Ref. 308

The main connection between light and motion of bodies can be stated in a few words. If the speed of light were not invariant, observers would be able to move at the speed of light. Since light is a wave, such observers would see a wave standing still. However, electromagnetism forbids such a phenomenon. Therefore, observers cannot reach the speed of light. The speed of light is an invariant limit speed. In other words, tennis with light is not fun: the speed of light is always the same.

Albert Einstein

Albert Einstein (b. 1879 Ulm, d. 1955 Princeton) was one of the greatest physicists and of the greatest thinkers ever. In 1905, he published three important papers: one about Brownian motion, one about special relativity, and one about the idea of light quanta. The first paper showed definitely that matter is made of atoms; the second showed the invariance of the speed of light; and the third paper was one of the starting points of quantum theory. Each paper was worth a Nobel Prize, but he was awarded the prize only

---

Page 732 why this is the case.

The speed of light is also not far from the speed of neutrinos. This was shown most spectacularly by the observation of a supernova in 1987, when the flash and the neutrino pulse arrived a 12 seconds apart. (It is not known whether the difference is due to speed differences or to a different starting point of the two flashes.) What is the first digit for which the two speed values could differ, knowing that the supernova was $1.7 \cdot 10^5$ light years away?

Challenge 623 s

Experiments also show that the speed of light is the same in all directions of space, to at least 21 digits of precision. Other data, taken from gamma ray bursts, show that the speed of light is independent of frequency, to at least 20 digits of precision.

A maximum local energy speed value c is consistent	1 – check that all consequences, however weird, are confirmed by observation 2 – deduce the theory of special relativity from it and check it

for the last one. Also in 1905, he proved the famous formula $E_0 = mc^2$ (published in early 1906), possibly triggered by an idea of Olinto De Pretto. Although Einstein was one of the founders of quantum theory, he later turned against it. His famous discussions with his friend Niels Bohr nevertheless helped to clarify the field in its most counter-intuitive aspects. He explained the Einstein–de Haas effect which proves that magnetism is due to motion inside materials. In 1915 and 1916, he published his highest achievement: the general theory of relativity, one of the most beautiful and remarkable works of science.

Page 447

Page 498

Being Jewish and famous, Einstein was a favourite target of attacks and discrimination by the National Socialist movement; in 1933 he emigrated to the USA. He was not only a great physicist, but also a great thinker; his collection of thoughts about topics outside physics are well worth reading.

Ref. 307

Anyone interested in emulating Einstein should know that he published many papers, and that many of them were wrong; he would then correct the results in subsequent papers, and then do so again. This happened so frequently that he made fun of himself about it. Einstein realized the famous definition of a genius as a person who makes the largest possible number of mistakes in the shortest possible time.

The speed of light as an invariant limit speed

Observers cannot reach the speed of light. Equivalently, no object can reach the speed of light. In other words, not only is light the standard of speed; it is also the maximal speed in nature. In short, the velocity v of any physical system in nature (i.e., any localized mass or energy) is bound by

$$v \leqslant c \,. \tag{136}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

This relation is the basis of special relativity; in fact, the full theory of special relativity is contained in it. The maximum speed implies many fascinating results: it leads to observer-varying time and length intervals, to an intimate relation between mass and energy, and to the existence of event horizons, as we will see.

Already in 1895, the discussion of viewpoint invariance had been called the *theory of relativity* by Henri Poincaré.* Einstein often regretted that the theory was called 'Relativitätstheorie' or 'theory of relativity'. The expression was already in vogue and had been proposed years before by Henri Poincaré; Einstein would have preferred the name 'Invarianztheorie' or 'theory of invariance', but was not able to change the name any more. Thus Einstein called the description of motion *without* gravity the theory of *special* relativity, and the description of motion *with* gravity the theory of *general* relativity. Both fields are full of fascinating and counter-intuitive results.

Ref. 309
Ref. 306

Can an invariant limit speed exist in nature? Table 50 shows that we need to explore three points to accept the idea. We need to show that no higher speed is *observed*, that no higher energy speed *can* ever be observed, and show that *all* consequences of invariance, however weird they may be, apply to nature. In fact, this is the theory of special relativity and thus is all we do in the remaining of this chapter.

The invariance of the speed of light is in complete contrast with Galilean mechanics, which describes the behaviour of stones, and proves that Galilean mechanics is *wrong* at high velocities. At low velocities the description remains good, because the error is small. But if we want a description valid at *all* velocities, we have to discard Galilean mechanics. For example, when we play tennis we use the fact that by hitting the ball in the right way, we can increase or decrease its speed. But with light this is impossible. Even if we take an aeroplane and fly after a light beam, it still moves away with the same speed. And astonishingly, all experiments confirms this weird behaviour.

If we accelerate a bus we are driving, the cars on the other side of the road pass by with higher and higher speeds. For light, experiment shows that this is *not* so: light always passes by with the *same* speed.** Light does not behave like cars or any other matter object. Again, all experiments confirm this weird behaviour.

Why exactly is the invariance of the speed of light almost unbelievable, even though the measurements show it unambiguously? Take two observers O and Ω (pronounced 'omega') moving with relative velocity v, such as two cars on opposite sides of the street. Imagine that at the moment they pass each other, a light flash is emitted by a lamp in O. The light flash moves through positions $x(t)$ for O and through positions $\xi(\tau)$ (pronounced 'xi of tau') for Ω. Since the speed of light is the same for both, we have

$$\frac{x}{t} = c = \frac{\xi}{\tau} \,. \tag{137}$$

* Henri Poincaré (1854–1912), important French mathematician and physicist. Poincaré was one of the most productive men of his time, advancing relativity, quantum theory, and many parts of mathematics.

The most beautiful and simple introduction to relativity is still that given by Albert Einstein himself, for example in *Über die spezielle und allgemeine Relativitätstheorie*, Vieweg, 1917 and 1997, or in *The Meaning of Relativity*, Methuen, 1951. It has taken a century for books almost as beautiful to appear, such as the text by Taylor and Wheeler.

Ref. 311, Ref. 312

** Indeed, even with the current measurement precision of $2 \cdot 10^{-13}$, we cannot discern any changes of the speed of light with the speed of the observer.

Ref. 304

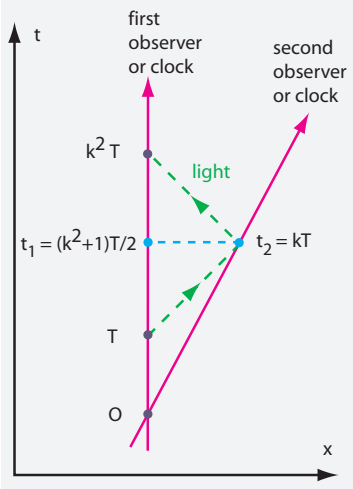

FIGURE 230 A drawing containing most of special relativity, including the expressions for time dilation and for the Lorentz transformation

However, in the situation described, we obviously have $x \neq \xi$. In other words, the constancy of the speed of light implies that $t \neq \tau$, i.e., that *time is different for observers moving relative to each other*. Time is thus not unique. This surprising result, which has been confirmed by many experiments, was first stated clearly in 1905 by Albert Einstein. Though many others knew about the invariance of c, only the young Einstein had the courage to say that time is observer-dependent, and to face the consequences. Let us do so as well.

Challenge 624 e

Ref. 310

One remark is in order. The speed of light is a limit speed. What is meant with this statement is that the speed of light *in vacuum* is a limit speed. For example, particles can indeed move faster than the speed of light *in matter*, as long as they move slower than the speed of light *in vacuum*. This is regularly observed. If the particle is charged, this situation gives rise to the so-called *Vavilov–Čerenkov radiation*. It corresponds to the V-shaped wave created by a motor boat on the sea or the cone-shaped shock wave around an aeroplane moving faster than the speed of sound. Vavilov–Čerenkov radiation is regularly observed; for example it is the cause of the blue glow of the water in nuclear reactors. Incidentally, the speed of light in matter can be quite low: in the centre of the Sun, the speed of light is estimated to be only around 10 km/year = 0.3 mm/s, and even in the laboratory, for some materials, it has been found to be as low as 0.3 m/s. In the following chapters, when we use the term 'speed of light', we mean the speed of light in vacuum. In fact, the speed of light in air is smaller than that in vacuum only by a fraction of one per cent, so that in most cases, the difference between air and vacuum can be neglected.

Ref. 313, Ref. 314

Special relativity with a few lines

The speed of light is invariant and constant for all observers. We can thus deduce all relations between what two different observers measure with the help of Figure 230. It shows two observers moving with constant speed against each other in space-time, with the first sending a light flash to the second, from where it is reflected back to the first.

Ref. 315

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

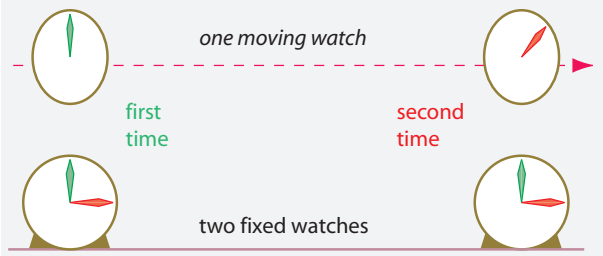

FIGURE 231 Moving clocks go slow: moving clocks mark time more slowly that do stationary clocks

Since light speed is constant, light is the only way to compare time and space coordinates for two distant observers. Two distant clocks (like two distant metre bars) can only be compared, or synchronized, using light or radio flashes. Since light speed is constant, all light paths in the same direction are parallel in such diagrams.

A constant relative speed between two observers implies that a constant factor k re-
Challenge 625 s lates the time coordinates of events. (Why is the relation linear?) If a flash starts at a time T as measured for the first observer, it arrives at the second at time kT, and then back
Challenge 626 s again at the first at time k^2T. The drawing shows that

$$k = \sqrt{\frac{c+v}{c-v}} \quad \text{or} \quad \frac{v}{c} = \frac{k^2-1}{k^2+1} \,. \tag{138}$$

Page 412 This factor will appear again in the Doppler effect.*

The figure also shows that the time coordinate t_1 assigned by the first observer to the moment in which the light is reflected is different from the coordinate t_2 assigned by the second observer. Time is indeed different for two observers in relative motion. Figure 231 illustrates the result.

The *time dilation factor* between the two time coordinates is found from Figure 230 by comparing the values t_1 and t_2; it is given by

$$\frac{t_1}{t_2} = \frac{1}{\sqrt{1-\frac{v^2}{c^2}}} = \gamma(v) \,. \tag{139}$$

Time intervals for a moving observer are *shorter* by this factor γ; the time dilation factor is always larger than 1. In other words, *moving clocks go slower*. For everyday speeds the
Challenge 627 e effect is tiny. That is why we do not detect time differences in everyday life. Nevertheless, Galilean physics is not correct for speeds near that of light. The same factor γ also appears in the formula $E = \gamma mc^2$, which we will deduce below. Expression (138) or (139) is the only piece of mathematics needed in special relativity: all other results derive from it.

If a light flash is sent forward starting from the second observer and reflected back, he will make the same statement: for him, the first clock is moving, and also for him, the moving clock marks time more slowly. *Each of the observers observes that the other clock marks time more slowly.* The situation is similar to that of two men comparing the number

* The explanation of relativity using the factor k is often called *k-calculus*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of steps between two identical ladders that are not parallel. A man on either ladder will always observe that the steps of the *other* ladder are shorter. For another analogy, take two people moving away from each other: each of them notes that the other gets smaller as their distance increases.

Naturally, many people have tried to find arguments to avoid the strange conclusion that time differs from observer to observer. But none have succeeded, and experimental results confirm this conclusion. Let us have a look at some of them.

Acceleration of light and the Doppler effect

Light *can* be accelerated. Every mirror does this! We will see in the chapter on electromagnetism that matter also has the power to *bend* light, and thus to accelerate it. However, it will turn out that all these methods only change the *direction* of propagation; none has the power to change the *speed* of light in a vacuum. In short, light is an example of a motion that cannot be stopped. There are only a few other such examples. Can you name one?

Page 737

Challenge 628 s

What would happen if we could accelerate light to higher speeds? For this to be possible, light would have to be made of *massive* particles. If light had mass, it would be necessary to distinguish the 'massless energy speed' c from the speed of light c_L, which would be lower and would depend on the kinetic energy of those massive particles. The speed of light would not be constant, but the massless energy speed would still be so. Massive light particles could be captured, stopped and stored in a box. Such boxes would make electric illumination unnecessary; it would be sufficient to store some daylight in them and release the light, slowly, during the following night, maybe after giving it a push to speed it up.*

Physicists have tested the possibility of massive light in quite some detail. Observations now put any possible mass of light (particles) at less than $1.3 \cdot 10^{-52}$ kg from terrestrial experiments, and at less than $4 \cdot 10^{-62}$ kg from astrophysical arguments (which are slightly less compelling). In other words, light is not heavy, light is light.

Ref. 316, Ref. 317

But what happens when light hits a *moving* mirror? If the speed of light does not change, something else must. The situation is akin to that of a light source moving with respect to the receiver: the receiver will observe a *different colour* from that observed by the sender. This is called the *Doppler effect*. Christian Doppler** was the first to study the frequency shift in the case of sound waves – the well-known change in whistle tone between approaching and departing trains – and to extend the concept to the case of light waves. As we will see later on, light is (also) a wave, and its colour is determined by its frequency, or equivalently, by its wavelength λ. Like the tone change for moving trains, Doppler realized that a moving light source produces a colour at the receiver that is different from the colour at the source. Simple geometry, and the conservation of the number of maxima and minima, leads to the result

Challenge 629 e

* Incidentally, massive light would also have *longitudinal* polarization modes. This is in contrast to observations, which show that light is polarized exclusively *transversally* to the propagation direction.

** Christian Andreas Doppler (b. 1803 Salzburg, d. 1853 Venezia), Austrian physicist. Doppler studied the effect named after him for sound and light. Already in 1842 he predicted (correctly) that one day we would be able to use the effect to measure the motion of distant stars by looking at their colours.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

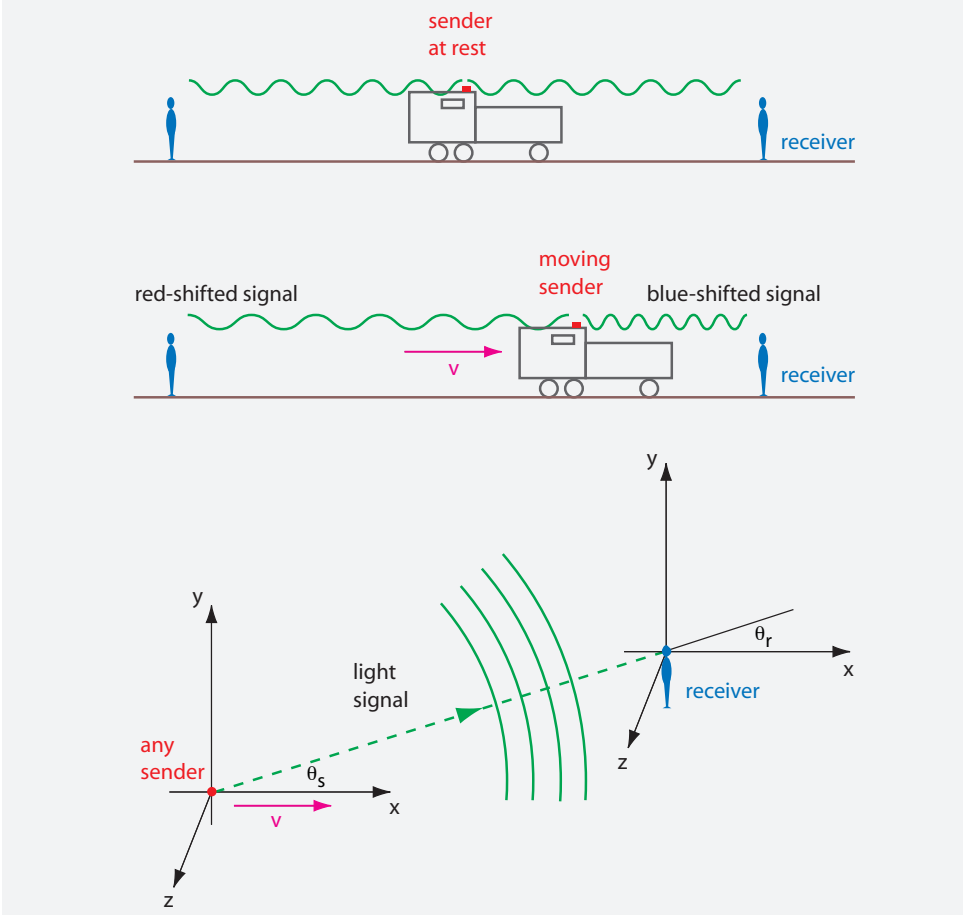

FIGURE 232 The set-up for the observation of the Doppler effect in one and three dimensions: waves emitted by an approaching source arrive with higher frequency and shorter wavelength, in contrast to waves emitted by a departing source

$$\frac{\lambda_r}{\lambda_s} = \frac{1}{\sqrt{1-v^2/c^2}}\left(1-\frac{v}{c}\cos\theta_r\right) = \gamma\left(1-\frac{v}{c}\cos\theta_r\right) . \qquad (140)$$

The variables v and θ_r in this expression are defined in Figure 232. Light from an approaching source is thus blue-shifted, whereas light from a departing source is red-shifted. The first observation of the Doppler effect for light was made by Johannes Stark* in 1905, who studied the light emitted by moving atoms. All subsequent experiments

* Johannes Stark (1874–1957), discovered in 1905 the optical Doppler effect in channel rays, and in 1913 the splitting of spectral lines in electrical fields, nowadays called the Stark effect. For these two discoveries he received the 1919 Nobel Prize for physics. He left his professorship in 1922 and later turned into a full-blown National Socialist. A member of the NSDAP from 1930 onwards, he became known for aggressively criticizing other people's statements about nature purely for ideological reasons; he became rightly despised by the academic community all over the world.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

confirmed the calculated colour shift within measurement errors; the latest checks have found agreement to within two parts per million. Ref. 318

In contrast to sound waves, a colour change is also found when the motion is *transverse* to the light signal. Thus, a yellow rod in rapid motion across the field of view will have a blue leading edge and a red trailing edge prior to the closest approach to the observer. The colours result from a combination of the longitudinal (first-order) Doppler shift and the transverse (second-order) Doppler shift. At a particular angle $\theta_{\text{unshifted}}$ the colours will be the same. (How does the wavelength change in the purely transverse case? What is the expression for $\theta_{\text{unshifted}}$ in terms of v?) Challenge 630 s

The colour shift is used in many applications. Almost all solid bodies are mirrors for radio waves. Many buildings have doors that open automatically when one approaches. A little sensor above the door detects the approaching person. It usually does this by measuring the Doppler effect of radio waves emitted by the sensor and reflected by the approaching person. (We will see later that radio waves and light are manifestations of the same phenomenon.) So the doors open whenever something moves towards them. Police radar also uses the Doppler effect, this time to measure the speed of cars.* Page 732

The Doppler effect also makes it possible to measure the velocity of light sources. Indeed, it is commonly used to measure the speed of distant stars. In these cases, the Doppler shift is often characterized by the *red-shift number* z, defined with the help of wavelength λ or frequency f by

$$z = \frac{\Delta\lambda}{\lambda} = \frac{f_S}{f_R} - 1 = \sqrt{\frac{c+v}{c-v}} - 1 \,. \tag{141}$$

Can you imagine how the number z is determined? Typical values for z for light sources in the sky range from −0.1 to 3.5, but higher values, up to more than 10, have also been found. Can you determine the corresponding speeds? How can they be so high? Challenge 632 s Challenge 633 s

In summary, whenever one tries to change the *speed* of light, one only manages to change its *colour*. That is the Doppler effect. In short, acceleration of light leads to colour change. This connection leads to a puzzle: we know from classical physics that when light passes a large mass, such as a star, it is deflected. Does this deflection lead to a Doppler shift? Page 161 Challenge 634 s

The difference between light and sound

The Doppler effect for light is much more fundamental than the Doppler effect for sound. Even if the speed of light were not yet known to be constant, this effect alone would *prove* that time is different for observers moving relative to each other. Why? Time is what we read from our watch. In order to determine whether another watch is synchronized with our own one, we look at both watches. In short, we need to use light signals to synchronize clocks. Now, any change in the colour of light moving from one observer to another necessarily implies that their watches run differently, and thus that time is *different* for the two of them. One way to see this is to note that also a light source is a clock – 'ticking' very rapidly. So if two observers see different colours from the same Ref. 319

Challenge 631 s * At what speed does a red traffic light appear green?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

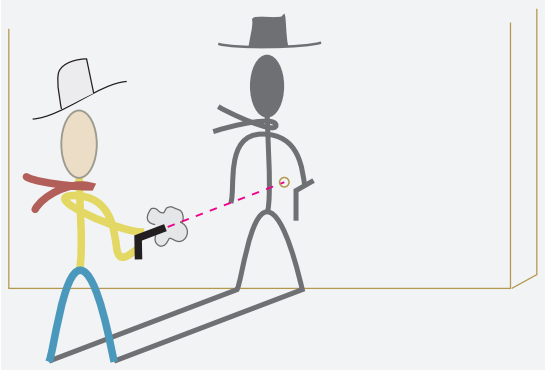

FIGURE 233 Lucky Luke

source, they measure different numbers of oscillations for the same clock. In other words, time is different for observers moving against each other. Indeed, equation (138) implies that the whole of relativity follows from the full Doppler effect for light. (Can you confirm that the connection between observer-dependent frequencies and observer-dependent time breaks down in the case of the Doppler effect for *sound*?)

Challenge 635 s

Why does the behaviour of light imply special relativity, while that of sound in air does not? The answer is that light is a limit for the motion of energy. Experience shows that there are supersonic aeroplanes, but there are no superluminal rockets. In other words, the limit $v \leqslant c$ is valid only if c is the speed of light, not if c is the speed of sound in air.

However, there is at least one system in nature where the speed of sound is indeed a limit speed for energy: the speed of sound is the limit speed for the motion of *dislocations* in crystalline solids. (We discuss this in detail later on.) As a result, the theory of special relativity is also valid for such dislocations, provided that the speed of light is replaced everywhere by the speed of sound! Dislocations obey the Lorentz transformations, show length contraction, and obey the famous energy formula $E = \gamma mc^2$. In all these effects the speed of sound c plays the same role for dislocations as the speed of light plays for general physical systems.

Page 1320

Ref. 320

Given special relativity is based on the statement that nothing can move faster than light, this statement needs to be carefully checked.

Can one shoot faster than one's shadow?

> Quid celerius umbra?*

For Lucky Luke to achieve the feat shown in Figure 233, his bullet has to move faster than the speed of light. (What about his hand?) In order to emulate Lucky Luke, we could take the largest practical amount of energy available, taking it directly from an electrical power station, and accelerate the lightest 'bullets' that can be handled, namely electrons. This experiment is carried out daily in particle accelerators such as the Large Electron Positron ring, the LEP, of 27 km circumference, located partly in France and partly in

Challenge 636 e

* 'What is faster than the shadow?' A motto often found on sundials.

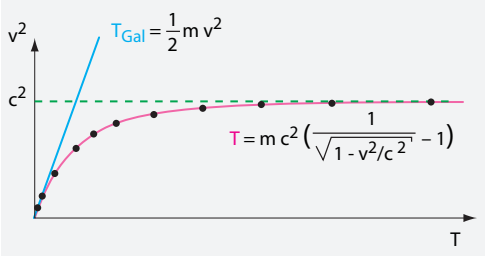

FIGURE 234 Experimental values (black dots) for the electron velocity v as function of their kinetic energy T, compared with the prediction of Galilean physics (blue) and that of special relativity (red)

Switzerland, near Geneva. There, 40 MW of electrical power (the same amount used by a small city) used to accelerate electrons and positrons to energies of over 16 nJ (104.5 GeV) each, and their speed was measured. The result is shown in Figure 234: even with these impressive means it is impossible to make electrons move more rapidly than light. (Can you imagine a way to measure energy and speed separately?) The speed–energy relation of Figure 234 is a consequence of the maximum speed, and is deduced below. These and many similar observations thus show that there is a *limit* to the velocity of objects. Bodies (and radiation) cannot move at velocities higher than the speed of light.* The accuracy of Galilean mechanics was taken for granted for more than three centuries, so that nobody ever thought of checking it; but when this was finally done, as in Figure 234, it was found to be wrong.

Ref. 321 Challenge 637 e Page 441

The people most unhappy with this limit are computer engineers: if the speed limit were higher, it would be possible to make faster microprocessors and thus faster computers; this would allow, for example, more rapid progress towards the construction of computers that understand and use language.

The existence of a limit speed runs counter to Galilean mechanics. In fact, it means that for velocities near that of light, say about 15 000 km/s or more, the expression $mv^2/2$ is *not* equal to the kinetic energy T of the particle. In fact, such high speeds are rather common: many families have an example in their home. Just calculate the speed of electrons inside a television, given that the transformer inside produces 30 kV.

Challenge 638 s

The observation of speed of light as a *limit* speed for objects is easily seen to be a consequence of its *constancy*. Bodies that can be at rest in one frame of reference obviously move more slowly than the maximum velocity (light) in that frame. Now, if something moves more slowly than something else for *one* observer, it does so for all other observers as well. (Trying to imagine a world in which this would not be so is interesting: funny things would happen, such as things interpenetrating each other.) Since the speed of light is the same for all observers, no object can move faster than light, for every observer.

Challenge 639 d

We conclude that the maximum speed is the speed of *massless* entities. Electromagnetic waves, including light, are the only known entities that can travel at the maximum

* There are still people who refuse to accept these results, as well as the ensuing theory of relativity. Every physicist should enjoy the experience, at least once in his life, of conversing with one of these men. (Strangely, no woman has yet been reported as belonging to this group of people.) This can be done, for example, via the internet, in the sci.physics.relativity newsgroup. See also the www.crank.net website. Crackpots are a fascinating lot, especially since they teach the importance of *precision* in language and in reasoning, which they all, without exception, neglect. Encounters with several of them provided the inspiration for this chapter.

Ref. 322

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

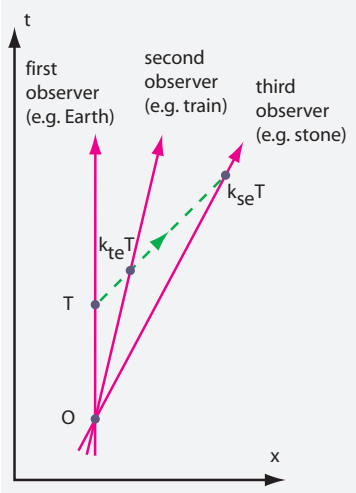

FIGURE 235 How to deduce the composition of velocities

speed. Gravitational waves are also predicted to achieve maximum speed. Though the speed of neutrinos cannot be distinguished experimentally from the maximum speed, recent experiments suggest that they do have a tiny mass. Ref. 323

Conversely, if a phenomenon exists whose speed is the limit speed for one observer, then this limit speed must necessarily be the same for all observers. Is the connection between limit property and observer invariance generally valid in nature? Challenge 640 e Challenge 641 r

The composition of velocities

If the speed of light is a limit, no attempt to exceed it can succeed. This implies that when velocities are composed, as when one throws a stone while running, the values cannot simply be added. If a train is travelling at velocity v_{te} relative to the Earth, and somebody throws a stone inside it with velocity v_{st} relative to the train in the same direction, it is usually assumed as evident that the velocity of the stone relative to the Earth is given by $v_{se} = v_{st} + v_{te}$. In fact, both reasoning and measurement show a different result.

The existence of a maximum speed, together with Figure 235, implies that the k-factors must satisfy $k_{se} = k_{st}k_{te}$.* Then we only have to insert the relation (138) between each k-factor and the respective speed to get Page 408 Challenge 642 e

$$v_{se} = \frac{v_{st} + v_{te}}{1 + v_{st}v_{te}/c^2} \,. \tag{142}$$

This is called the *velocity composition formula*. The result is never larger than c and is always smaller than the naive sum of the velocities.** Expression (142) has been confirmed by all of the millions of cases for which it has been checked. You may check that it simplifies to the naive sum for everyday life values. Challenge 643 e Page 441, page 692 Ref. 317

* By taking the (natural) logarithm of this equation, one can define a quantity, the *rapidity*, that measures

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Observers and the principle of special relativity

Special relativity is built on a simple principle:

▷ *The maximum speed of energy transport is the same for all observers.*

Ref. 325 Or, as Hendrik Lorentz* liked to say, the equivalent:

▷ *The speed v of a physical system is bound by*

$$v \leqslant c \tag{143}$$

for all observers, where c is the speed of light.

This independence of the speed of light from the observer was checked with high precision by Michelson and Morley** in the years from 1887 onwards. It has been confirmed in all subsequent experiments; the most precise to date, by Stephan Schiller and his team, achieved a precision of 10^{-14} and is shown in Figure 236.

Ref. 326 Ref. 327

In fact, special relativity is also confirmed by all the precision experiments that were performed *before* it was formulated. You can even confirm it yourself at home. The way to do this is shown in the section on electrodynamics.

Page 692

The existence of a limit speed has several interesting consequences. To explore them, let us keep the rest of Galilean physics intact.*** The limit speed is the speed of light. It is constant for all observers. This constancy implies:

— In a closed free-floating room, there is no way to tell the speed of the room.
— There is no notion of absolute rest (or space): rest (like space) is an observer-dependent concept.****

---

the speed and is additive.

Ref. 324 ** One can also deduce the Lorentz transformation directly from this expression.

* Hendrik Antoon Lorentz (b. 1853 Arnhem, d. 1928 Haarlem) was, together with Boltzmann and Kelvin, one of the most important physicists of his time. He deduced the so-called Lorentz transformation and the Lorentz contraction from Maxwell's equation for the electrodynamic field. He was the first to understand, long before quantum theory confirmed the idea, that Maxwell's equations for the vacuum also describe matter and all its properties, as long as moving charged point particles – the electrons – are included. He showed this in particular for the dispersion of light, for the Zeeman effect, for the Hall effect and for the Faraday effect. He gave the correct description of the Lorentz force. In 1902, he received the physics Nobel Prize, together with Pieter Zeeman. Outside physics, he was active in the internationalization of scientific collaborations. He was also instrumental in the creation of the largest human-made structures on Earth: the polders of the Zuyder Zee.

** Albert Abraham Michelson (b. 1852 Strelno, d. 1931 Pasadena), Prussian–Polish–US-American physicist, awarded the Nobel Prize in Physics in 1907. Michelson called the set-up he devised an *interferometer*, a term still in use today. Edward William Morley (1838–1923), US-American chemist, was Michelson's friend and long-time collaborator.

Page 132 *** This point is essential. For example, Galilean physics states that only *relative* motion is physical. Galilean physics also excludes various mathematically possible ways to realize a constant light speed that would contradict everyday life.

Einstein's original 1905 paper starts from two principles: the constancy of the speed of light and the equivalence of all inertial observers. The latter principle had already been stated in 1632 by Galileo; only the constancy of the speed of light was new. Despite this fact, the new theory was named – by Poincaré – after the old principle, instead of calling it 'invariance theory', as Einstein would have preferred.

Ref. 309

Challenge 644 s **** Can you give the argument leading to this deduction?

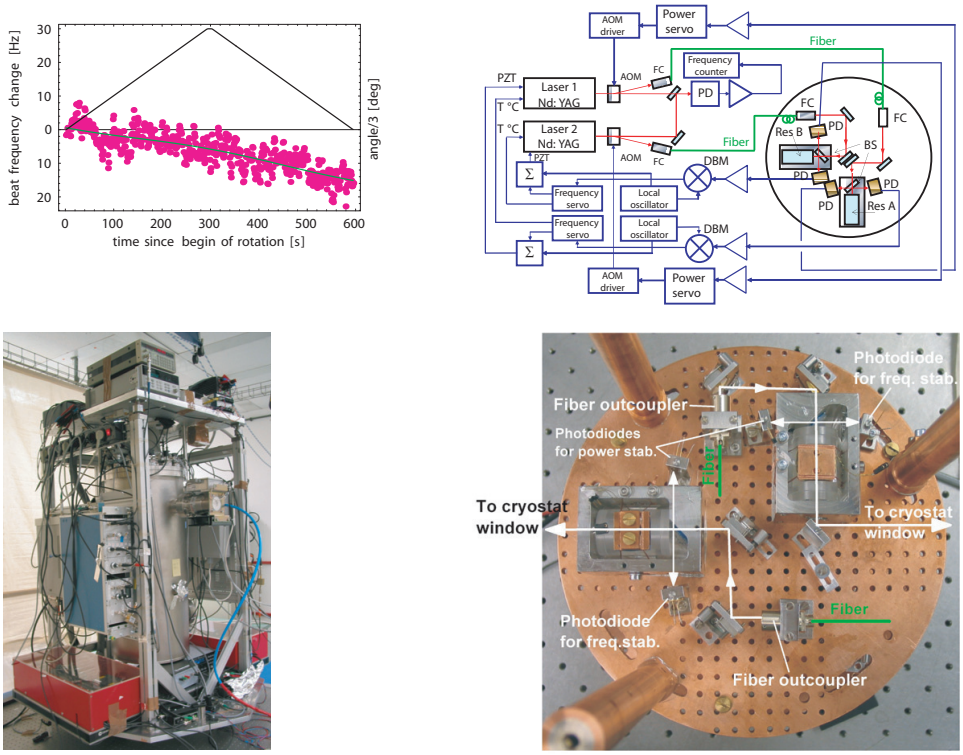

FIGURE 236 The result, the schematics and the cryostat set-up for the most precise Michelson–Morley experiment performed to date (© Stephan Schiller)

— Time depends on the observer; time is not absolute.

More interesting and specific conclusions can be drawn when two additional conditions are assumed. First, we study situations where gravitation can be neglected. (If this not the case, we need *general* relativity to describe the system.) Secondly, we also assume that the data about the bodies under study – their speed, their position, etc. – can be gathered without disturbing them. (If this not the case, we need *quantum theory* to describe the system.)

To deduce the *precise* way in which the different time intervals and lengths measured by two observers are related to each other, we take an additional simplifying step. We start with a situation where no interaction plays a role. In other words, we start with *relativistic kinematics* of bodies moving without disturbance.

If an undisturbed body is observed to travel along a straight line with a constant velocity (or to stay at rest), one calls the observer *inertial*, and the coordinates used by the observer an *inertial frame of reference*. Every inertial observer is itself in undisturbed motion. Examples of inertial observers (or frames) thus include – in *two* dimensions – those moving on a frictionless ice surface or on the floor inside a smoothly running train or ship; for a full example – in all *three* spatial dimensions – we can take a cosmonaut travelling in a space-ship as long as the engine is switched off. Inertial observers in

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

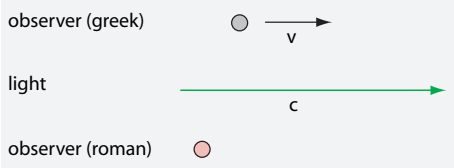

FIGURE 237 Two inertial observers and a beam of light

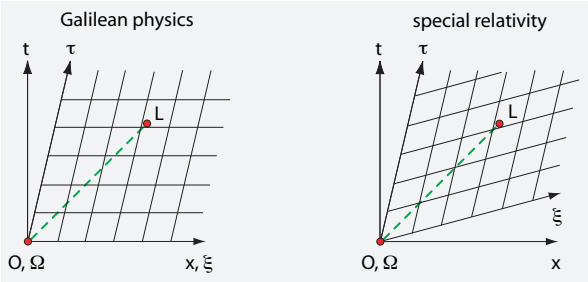

FIGURE 238 Space-time diagrams for light seen from two different observers using coordinates (t, x) and (τ, ξ)

three dimensions might also be called *free-floating* observers. They are thus not so common. Non-inertial observers are much more common. Can you confirm this? Inertial observers are the most simple ones, and they form a special set:

Challenge 645 e

— Any two inertial observers move with constant velocity relative to each other (as longs as gravity plays no role, as assumed above).
— All inertial observers are equivalent: they describe the world with the same equations. Because it implies the lack of absolute space and time, this statement was called the *principle of relativity* by Henri Poincaré. However, the *essence* of relativity is the existence of a limit speed.

To see how measured length and space intervals change from one observer to the other, we assume two inertial observers, a Roman one using coordinates x, y, z and t, and a Greek one using coordinates ξ, υ, ζ and τ,* that move with velocity $\boldsymbol{v}$ relative to each other. The axes are chosen in such a way that the velocity points in the x-direction. The constancy of the speed of light in any direction for any two observers means that for the motion of light the coordinate differentials are related by

$$0 = (c\mathrm{d}t)^2 - (\mathrm{d}x)^2 - (\mathrm{d}y)^2 - (\mathrm{d}z)^2 = (c\mathrm{d}\tau)^2 - (\mathrm{d}\xi)^2 - (\mathrm{d}\upsilon)^2 - (\mathrm{d}\zeta)^2 \,. \qquad (144)$$

Assume also that a flash lamp at rest for the Greek observer, thus with $\mathrm{d}\xi = 0$, produces two flashes separated by a time interval $\mathrm{d}\tau$. For the Roman observer, the flash lamp moves with speed v, so that $\mathrm{d}x = v\mathrm{d}t$. Inserting this into the previous expression, and assuming linearity and speed direction independence for the general case, we find that intervals are related by

Challenge 646 e

* They are read as 'xi', 'upsilon', 'zeta' and 'tau'. The names, correspondences and pronunciations of all Greek letters are explained in Appendix A.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$\begin{aligned} \mathrm{d}t &= \gamma(\mathrm{d}\tau + v\mathrm{d}\xi/c^2) = \frac{\mathrm{d}\tau + v\mathrm{d}\xi/c^2}{\sqrt{1 - v^2/c^2}} \quad \text{with} \quad v = \mathrm{d}x/\mathrm{d}t \\ \mathrm{d}x &= \gamma(\mathrm{d}\xi + v\mathrm{d}\tau) = \frac{\mathrm{d}\xi + v\mathrm{d}\tau}{\sqrt{1 - v^2/c^2}} \\ \mathrm{d}y &= \mathrm{d}v \\ \mathrm{d}z &= \mathrm{d}\zeta \ . \end{aligned} \tag{145}$$

These expressions describe how length and time intervals measured by different observers are related. At relative speeds v that are small compared to the velocity of light, such as occur in everyday life, the time intervals are essentially equal; the *stretch factor* or *relativistic correction* or *relativistic contraction* γ is then equal to 1 for all practical purposes. However, for velocities *near* that of light the measurements of the two observers give different values. In these cases, space and time *mix*, as shown in Figure 238.

The expressions (145) are also strange in another respect. When two observers look at each other, each of them claims to measure shorter intervals than the other. In other words, special relativity shows that the grass on the other side of the fence is always *shorter* – if one rides along beside the fence on a bicycle and if the grass is inclined. We explore this bizarre result in more detail shortly.

Challenge 647 s

The stretch factor γ is equal to 1 for most practical purposes in everyday life. The largest value humans have ever achieved is about $2 \cdot 10^5$; the largest observed value in nature is about 10^{12}. Can you imagine where they occur?

Challenge 648 s

Once we know how space and time *intervals* change, we can easily deduce how *coordinates* change. Figures 237 and 238 show that the x coordinate of an event L is the sum of two intervals: the ξ coordinate and the length of the distance between the two origins. In other words, we have

$$\xi = \gamma(x - vt) \quad \text{and} \quad v = \frac{\mathrm{d}x}{\mathrm{d}t} \ . \tag{146}$$

Using the invariance of the space-time interval, we get

$$\tau = \gamma(t - xv/c^2) \ . \tag{147}$$

Henri Poincaré called these two relations the *Lorentz transformations of space and time* after their discoverer, the Dutch physicist Hendrik Antoon Lorentz.* In one of the most beautiful discoveries of physics, in 1892 and 1904, Lorentz deduced these relations from the equations of electrodynamics, where they had been lying, waiting to be discovered, since 1865.** In that year James Clerk Maxwell had published the equations that describe everything electric and magnetic. However, it was only Einstein who first understood that t and τ, as well as x and ξ, are equally important and thus equally valid descriptions of space and time.

Ref. 328

Page 706

* For information about Hendrik Antoon Lorentz, see page 418.

** The same discovery had been published first in 1887 by the German physicist Woldemar Voigt (1850–1919); Voigt – pronounced 'Fohgt' – was also the discoverer of the Voigt effect and the Voigt tensor. Independently, in 1889, the Irishman George F. Fitzgerald also found the result.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The Lorentz transformation describes the change of viewpoint from one inertial frame to a second, moving one. This change of viewpoint is called a (Lorentz) *boost*. The formulae (146) and (147) for the boost are central to the theories of relativity, both special and general. In fact, the mathematics of special relativity will not get more difficult than that: if you know what a square root is, you can study special relativity in all its beauty.

Many alternative formulae for boosts have been explored, such as expressions in which the relative acceleration of the two observers is included, as well as the relative
Ref. 329 velocity. However, they had all to be discarded after comparing their predictions with experimental results. Before we have a look at such experiments, we continue with a few logical deductions from the boost relations.

What is space-time?

> Von Stund' an sollen Raum für sich und Zeit für sich völlig zu Schatten herabsinken und nur noch eine Art Union der beiden soll Selbstständigkeit bewaren.*
>
> Hermann Minkowski.

The Lorentz transformations tell us something important: that space and time are two aspects of the same basic entity. They 'mix' in different ways for different observers. This fact is commonly expressed by stating that time is the *fourth dimension*. This makes sense because the common basic entity – called *space-time* – can be defined as the set of all events, events being described by four coordinates in time and space, and because the
Challenge 649 s set of all events has the properties of a manifold.** (Can you confirm this?)

In other words, the existence of a maximum speed in nature forces us to introduce a space-time manifold for the description of nature. In the theory of special relativity, the space-time manifold is characterized by a simple property: the *space-time interval* $\mathrm{d}i$
Ref. 330 between two nearby events, defined as

$$\mathrm{d}i^2 = c^2\mathrm{d}t^2 - \mathrm{d}x^2 - \mathrm{d}y^2 - \mathrm{d}z^2 = c^2\mathrm{d}t^2\left(1 - \frac{v^2}{c^2}\right) , \tag{148}$$

is independent of the (inertial) observer. Such a space-time is also called Minkowski space-time, after Hermann Minkowski,*** the teacher of Albert Einstein; he was the first, in 1904, to define the concept of space-time and to understand its usefulness and importance.

The space-time interval $\mathrm{d}i$ of equation (148) has a simple interpretation. It is the time measured by an observer moving from event (t, x) to event $(t+\mathrm{d}t, x+\mathrm{d}x)$, the so-called *proper time*, multiplied by c. If we neglect the factor c, we could simply call it wristwatch time.

---

* 'Henceforth space by itself and time by itself shall completely fade into shadows and only a kind of union of the two shall preserve autonomy.' This famous statement was the starting sentence of Minkowski's 1908 talk at the meeting of the Gesellschaft für Naturforscher und Ärzte.

Page 897 ** The term 'manifold' is defined in Appendix B.

*** Hermann Minkowski (1864–1909), German mathematician. He had developed similar ideas to Einstein, but the latter was faster. Minkowski then developed the concept of space-time. Minkowski died suddenly at the age of 44.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

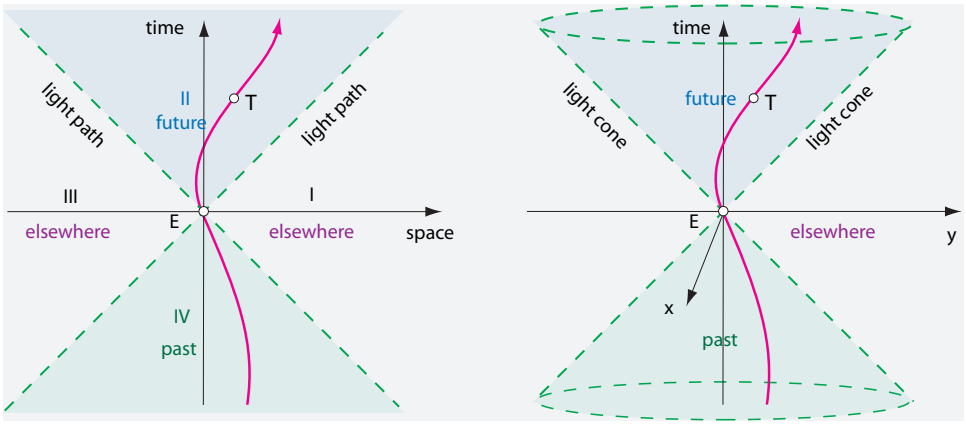

FIGURE 239 A space-time diagram for a moving object T seen from an inertial observer O in the case of one and two spatial dimensions; the slope of the curve at a point gives the speed that that point, and is thus never steeper than that of light

We *live* in a Minkowski space-time, so to speak. Minkowski space-time exists independently of things. And even though coordinate systems can be different from observer to observer, the underlying entity, space-time, is still *unique*, even though space and time by themselves are not.

How does Minkowski space-time differ from Galilean space-time, the combination of everyday space and time? Both space-times are manifolds, i.e., continuum sets of points, both have one temporal and three spatial dimensions, and both manifolds have the topology of the punctured sphere. (Can you confirm this?) Both manifolds are flat, i.e., free of curvature. In both cases, space is what is measured with a metre rule or with a light ray, and time is what is read from a clock. In both cases, space-time is fundamental; it is and remains the *background* and the *container* of things and events.

Challenge 650 s

The central difference, in fact the only one, is that Minkowski space-time, in contrast to the Galilean case, *mixes* space and time, and in particular, does so differently for observers with different speeds, as shown in Figure 238. That is why time is an observer-dependent concept.

The maximum speed in nature thus forces us to describe motion with space-time. That is interesting, because in space-time, speaking in simple terms, *motion does not exist*. Motion exists only in space. In space-time, nothing moves. For each point particle, space-time contains a world-line. In other words, instead of asking why motion exists, we can equivalently ask why space-time is criss-crossed by world-lines. At this point, we are still far from answering either question. What we can do is to explore *how* motion takes place.

Can we travel to the past? – Time and causality

We know that time is different for different observers. Does time nevertheless order events in sequences? The answer given by relativity is a clear 'yes and no'. Certain sets of events are not naturally ordered by time; others sets are. This is best seen in a space-time diagram.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Clearly, two events can be placed in sequence only if one event is the *cause* of the other. But this connection can only apply if the events exchange energy (e.g. through a signal). In other words, a relation of cause and effect between two events implies that energy or signals can travel from one event to the other; therefore, the speed connecting the two events must not be larger than the speed of light. Figure 239 shows that event E at the origin of the coordinate system can only be influenced by events in quadrant IV (the *past light cone*, when all space dimensions are included), and can itself influence only events in quadrant II (the *future light cone*). Events in quadrants I and III neither influence nor are influenced by event E: signal speed above that of light would be necessary to achieve that. The light cone defines the boundary between events that *can* be ordered with respect to their origin – namely those inside the cone – and those that *cannot* – those outside the cones, happening elsewhere for all observers. (Some people call all the events happening elsewhere the *present*.) So, time orders events only *partially*. For example, for two events that are not causally connected, their temporal order (or their simultaneity) depends on the observer!

In particular, the past light cone gives the complete set of events that can influence what happens at the origin. One says that the origin is *causally connected* only to the past light cone. This statement reflects the fact that any influence involves transport of energy, and thus cannot travel faster than the speed of light. Note that causal connection is an invariant concept: all observers agree on whether or not it applies to two given events.

Challenge 651 s Can you confirm this?

A vector inside the light cone is called *timelike*; one on the light cone is called *light-like* or *null*; and one outside the cone is called *spacelike*. For example, the *world-line* of an observer, i.e., the set of all events that make up its past and future history, consists of timelike events only. Time is the fourth dimension; it expands space to space-time and thus 'completes' space-time. This is the relevance of the fourth dimension to special relativity, no more and no less.

Special relativity thus teaches us that causality and time can be defined *only* because light cones exist. If transport of energy at speeds faster than that of light did exist, time could not be defined. Causality, i.e., the possibility of (partially) ordering events for all observers, is due to the existence of a maximal speed.

If the speed of light could be surpassed in some way, the future could influence the

Challenge 652 s past. Can you confirm this? In such situations, one would observe *acausal* effects. However, there is an everyday phenomenon which tells that the speed of light is indeed maximal: our memory. If the future could influence the past, we would also be able to *remember* the future. To put it in another way, if the future could influence the past, the second principle of thermodynamics would not be valid and our memory would not work.* No other data from everyday life or from experiments provide any evidence that the future can influence the past. In other words, *time travel to the past is impossible*. How the situation changes in quantum theory will be revealed later on. Interestingly, time travel to the future *is* possible, as we will see shortly.

* Another related result is slowly becoming common knowledge. Even if space-time had a nontrivial shape, such as a cylindrical topology with closed time-like curves, one still would not be able to travel into the

Ref. 331 past, in contrast to what many science fiction novels suggest. This is made clear by Stephen Blau in a recent pedagogical paper.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

CURIOSITIES ABOUT SPECIAL RELATIVITY

Let us start with a puzzle that helps to sharpen the concepts. Seen by an observer on an island, two lightning strokes hit simultaneously: one hits the island, and another, many miles away, the open sea. A second observer is a pilot in a relativistic aeroplane and happens to be just above the island. Which lightning hits first for the pilot?

For the pilot, the distant lightning, hitting the sea, hits first. But this is a trick question: despite being the one that hits first, the distant lightning is observed by the pilot to hit *after* the one on the island, because light from the distant hit needs time to reach him. However, the pilot can compensate for the propagation time and then deduces that the distant lightning hit first.

Challenge 653 e

Let us explore a few additional consequences of special relativity.

Faster than light: how far can we travel?

How far away from Earth can we travel, given that the trip should not last more than a lifetime, say 80 years, and given that we are allowed to use a rocket whose speed can approach the speed of light as closely as desired? Given the time t we are prepared to spend in a rocket, given the speed v of the rocket and assuming optimistically that it can accelerate and decelerate in a negligible amount of time, the distance d we can move away is given by

Challenge 654 e

$$d = \frac{vt}{\sqrt{1 - v^2/c^2}} \,. \tag{149}$$

The distance d is larger than ct already for $v > 0.71c$, and, if v is chosen large enough, it increases beyond all bounds! In other words, relativity does *not* limit the distance we can travel in a lifetime, and not even the distance we can travel in a single second. We could, in principle, roam the entire universe in less than a second. In situations such as these it makes sense to introduce the concept of *proper velocity* w, defined as

$$w = \frac{d}{t} = \frac{v}{\sqrt{1 - v^2/c^2}} = \gamma\, v \,. \tag{150}$$

As we have just seen, proper velocity is *not* limited by the speed of light; in fact the proper velocity of light itself is infinite.*

Synchronization and time travel – can a mother stay younger than her own daughter?

A maximum speed implies that time is different for different observers moving relative to each other. So we have to be careful about how we synchronize clocks that are far

* Using proper velocity, the relation given in equation (142) for the superposition of two velocities $\mathbf{w}_a = \gamma_a \mathbf{v}_a$ and $\mathbf{w}_b = \gamma_b \mathbf{v}_b$ simplifies to

Challenge 655 e

$$w_{s\parallel} = \gamma_a \gamma_b (v_a + v_{b\parallel}) \quad \text{and} \quad w_{s\perp} = w_{b\perp} \,, \tag{151}$$

where the signs $\parallel$ and $\perp$ designate the component in the direction of and the component perpendicular to $\mathbf{v}_a$, respectively. One can in fact express all of special relativity in terms of 'proper' quantities.

Ref. 332

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

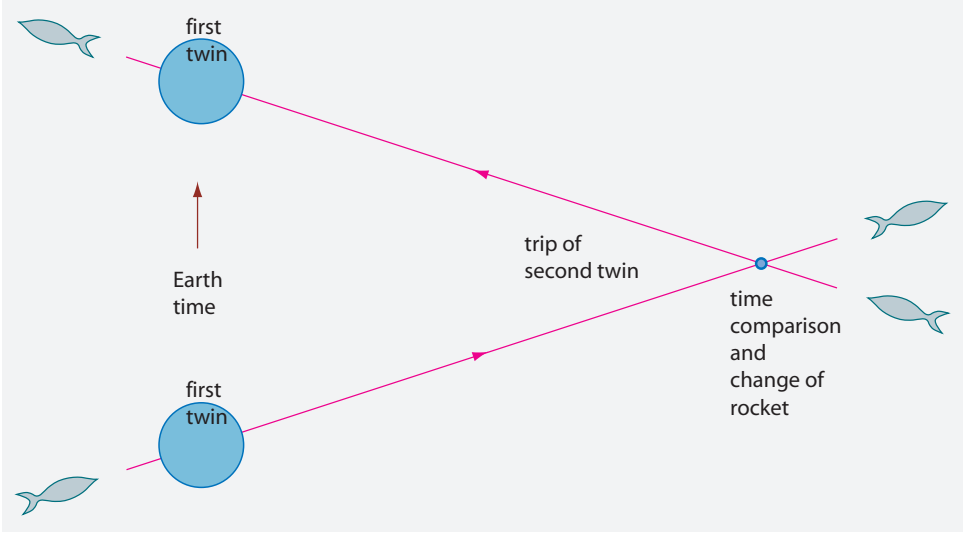

FIGURE 240 The twin paradox

apart, even if they are at rest with respect to each other in an inertial reference frame. For example, if we have two similar watches showing the same time, and if we carry one of them for a walk and back, they will show different times afterwards. This experiment has actually been performed several times and has fully confirmed the prediction of special relativity. The time difference for a person or a watch in an aeroplane travelling around the Earth once, at about 900 km/h, is of the order of 100 ns – not very noticeable in everyday life. In fact, the delay is easily calculated from the expression

Ref. 333, Ref. 334

$$\frac{t}{t'} = \gamma \,. \tag{152}$$

Human bodies are clocks; they show the elapsed time, usually called *age*, by various changes in their shape, weight, hair colour, etc. If a person goes on a long and fast trip, on her return she will have aged *less* than a second person who stayed at her (inertial) home.

The most famous illustration of this is the famous *twin paradox* (or *clock paradox*). An adventurous twin jumps on a relativistic rocket that leaves Earth and travels for many years. Far from Earth, he jumps on another relativistic rocket going the other way and returns to Earth. The trip is illustrated in Figure 240. At his arrival, he notes that his twin brother on Earth is much older than himself. Can you explain this result, especially the asymmetry between the two brothers? This result has also been confirmed in many experiments.

Ref. 335

Special relativity thus confirms, in a surprising fashion, the well-known observation that those who travel a lot remain younger. The price of the retained youth is, however, that everything around one changes very much more quickly than if one is at rest with the environment.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

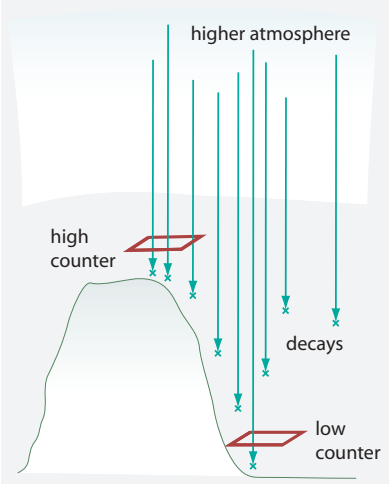

FIGURE 241 More muons than expected arrive at the ground because fast travel keeps them young

The twin paradox can also be seen as a confirmation of the possibility of time travel to the future. With the help of a fast rocket that comes back to its starting point, we can arrive at local times that we would never have reached within our lifetime by staying home. Alas, we can *never* return to the past.*

One of the simplest experiments confirming the prolonged youth of fast travellers involves the counting of muons. Muons are particles that are continuously formed in the upper atmosphere by cosmic radiation. Muons *at rest* (with respect to the measuring clock) have a finite half-life of 2.2 µs (or, at the speed of light, 660 m). After this amount of time, half of the muons have decayed. This half-life can be measured using simple muon counters. In addition, there exist special counters that only count muons travelling within a certain speed range, say from $0.9950c$ to $0.9954c$. One can put one of these special counters on top of a mountain and put another in the valley below, as shown in Figure 241. The first time this experiment was performed, the height difference was 1.9 km. Flying 1.9 km through the atmosphere at the mentioned speed takes about 6.4 µs. With the half-life just given, a naive calculation finds that only about 13% of the muons observed at the top should arrive at the lower site. However, it is observed that about 82% of the muons arrive below. The reason for this result is the relativistic time dilation. Indeed, at the mentioned speed, muons experience a time difference of only 0.62 µs during the travel from the mountain top to the valley. This shorter time yields a much lower number of lost muons than would be the case without time dilation; moreover, the measured percentage confirms the value of the predicted time dilation factor γ within experimental errors, as you may want to check. A similar effect is seen when relativistic muons are produced in accelerators.

Page 1222
Ref. 337
Challenge 656 s
Challenge 657 s

Half-life dilation has also been found for many other decaying systems, such as pions, hydrogen atoms, neon atoms and various nuclei, always confirming the predictions of

Ref. 336
* There are even special books on time travel, such as the well researched text by Nahin. Note that the concept of time travel has to be clearly defined; otherwise one has no answer to the clerk who calls his office chair a time machine, as sitting on it allows him to get to the future.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

special relativity. Since all bodies in nature are made of particles, the 'youth effect' of high speeds (usually called 'time dilation') applies to bodies of all sizes; indeed, it has not only been observed for particles, but also for lasers, radio transmitters and clocks. Ref. 317

If motion leads to time dilation, a clock on the Equator, constantly running around the Earth, should go slower than one at the poles. However, this prediction, which was made by Einstein himself, is incorrect. Ref. 338 The centrifugal acceleration leads to a reduction in gravitational acceleration that exactly cancels the increase due to the velocity. This story serves as a reminder to be careful when applying special relativity in situations involving gravity. Special relativity is only applicable when space-time is flat, not when gravity is present.

In short, a mother *can* stay younger than her daughter. We can also conclude that we cannot synchronize clocks at rest with respect to each other simply by walking, clock in hand, from one place to another. The correct way to do so is to exchange light signals. Challenge 658 s Can you describe how?

A precise definition of synchronization allows us to call two distant events simultaneous. In addition, special relativity shows that simultaneity depends on the observer. This is confirmed by all experiments performed so far.

However, the mother's wish is not easy to fulfil. Let us imagine that a mother is accelerated in a spaceship away from Earth at $10\,\mathrm{m/s^2}$ for ten years, then decelerates at $10\,\mathrm{m/s^2}$ for another ten years, then accelerates for ten additional years towards the Earth, and finally decelerates for ten final years in order to land safely back on our planet. The mother has taken 40 years for the trip. She got as far as 22 000 light years from Earth. At her return on Earth, 44 000 years have passed. All this seems fine, until we realize that the necessary amount of fuel, even for the most efficient engine imaginable, is so large that the mass returning from the trip is only one part in $2 \cdot 10^{19}$. Challenge 659 e The necessary amount of fuel does not exist on Earth.

Length contraction

The length of an object measured by an observer attached to the object is called its proper length. According to special relativity, the length measured by an inertial observer passing by is always smaller than the proper length. This result follows directly from the Lorentz transformations. Challenge 660 e

For a Ferrari driving at 300 km/h or 83 m/s, the length is contracted by 0.15 pm: less than the diameter of a proton. Seen from the Sun, the Earth moves at 30 km/s; this gives a length contraction of 6 cm. Neither of these effects has ever been measured. But larger effects could be. Let us explore some examples.

Imagine a pilot flying through a barn with two doors, one at each end. The plane is slightly longer than the barn, but moves so rapidly that its relativistically contracted length is shorter than the length of the barn. Can the farmer close the barn (at least for a short time) with the plane completely inside? The answer is positive. But why can the pilot not say the following: relative to him, the barn is contracted; therefore the plane does not fit inside the barn? The answer is shown in Figure 242. For the farmer, the doors close (and reopen) at the same time. For the pilot, they do not. For the farmer, the pilot is in the dark for a short time; for the pilot, the barn is never dark. (That is not completely true: Challenge 661 s can you work out the details?)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

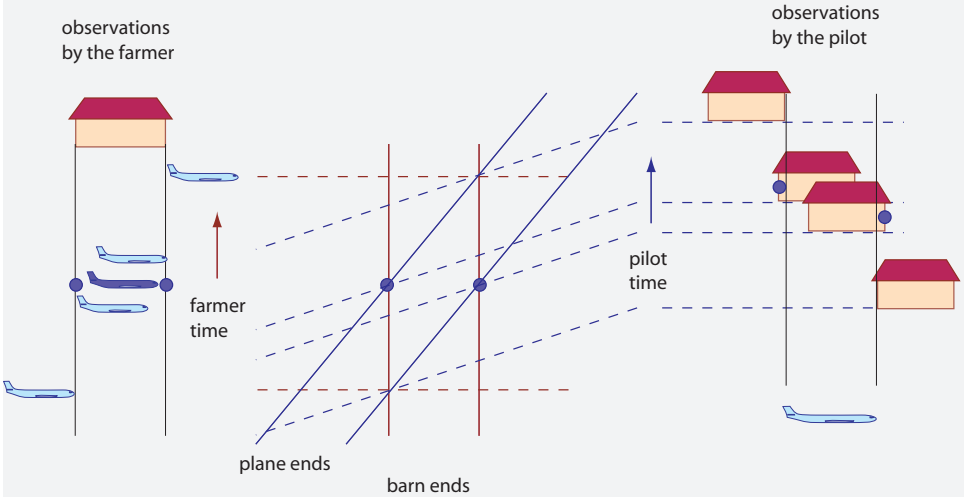

FIGURE 242 The observations of the pilot and the barn owner

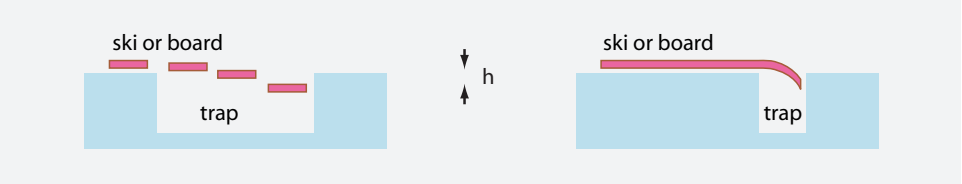

FIGURE 243 The observations of the trap digger and of the snowboarder, as (misleadingly) published in the literature

We now explore some variations of the general case. Can a rapid snowboarder fall into a hole that is a bit shorter than his board? Imagine him boarding so fast that the length contraction factor $\gamma = d/d'$ is 4.* For an observer on the ground, the snowboard is four times shorter, and when it passes over the hole, it will fall into it. However, for the boarder, it is the hole which is four times shorter; it seems that the snowboard cannot fall into it.

Ref. 339 More careful analysis shows that, in contrast to the observation of the hole digger, the snowboarder does not experience the board's shape as fixed: while passing over the hole, the boarder observes that the board takes on a parabolic shape and falls into the hole, Challenge 663 e as shown in Figure 243. Can you confirm this? In other words, shape is not an observer-invariant concept. (However, rigidity *is* observer-invariant, if defined properly; can you Challenge 664 s confirm this?)

Ref. 340 This explanation, though published, is not correct, as Harald van Lintel and Christian Gruber have pointed out. One should not forget to estimate the size of the effect. At relativistic speeds the time required for the hole to affect the full thickness of the board cannot be neglected. The snowboarder only sees his board take on a parabolic shape if it is extremely thin and flexible. For usual boards moving at relativistic speeds, the

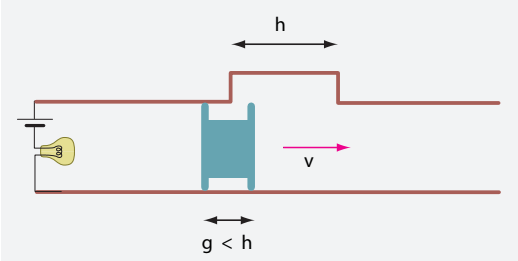

FIGURE 244 Does the conducting glider keep the lamp lit at large speeds?

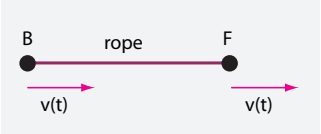

FIGURE 245 What happens to the rope?

Challenge 665 e snowboarder has no time to fall any appreciable height h or to bend into the hole before passing it. Figure 243 is so exaggerated that it is incorrect. The snowboarder would simply speed over the hole.

The paradoxes around length contraction become even more interesting in the case Ref. 341 of a conductive glider that makes electrical contact between two rails, as shown in Figure 244. The two rails are parallel, but one rail has a gap that is longer than the glider. Can you work out whether a lamp connected in series stays lit when the glider moves Challenge 666 s along the rails with relativistic speed? (Make the simplifying and not fully realistic assumption that electrical current flows as long and as soon as the glider touches the rails.) Do you get the same result for all observers? And what happens when the glider is longer than the detour? Or when it approaches the lamp from the other side of the detour? (Warning: this problem gives rise to *heated* debates!) What is unrealistic in this experiment?

Ref. 342 Another example of length contraction appears when two objects, say two cars, are connected over a distance d by a straight rope, as shown in Figure 245. Imagine that both are at rest at time $t = 0$ and are accelerated together in exactly the same way. The observer at rest will maintain that the two cars remain the same distance apart. On the other hand, the rope needs to span a distance $d' = d/\sqrt{1 - v^2/c^2}$, and thus has to expand when the two cars are accelerating. In other words, the rope will break. Is this prediction Challenge 667 s confirmed by observers on each of the two cars?

A funny – but quite unrealistic – example of length contraction is that of a submarine Ref. 343 moving horizontally. Imagine that the resting submarine has tuned its weight to float in water without any tendency to sink or to rise. Now the submarine moves (possibly with relativistic speed). The captain observes the water outside to be Lorentz contracted; thus the water is denser and he concludes that the submarine will rise. A nearby fish sees the submarine to be contracted, thus denser than water, and concludes that the submarine Challenge 668 s will sink. Who is wrong, and what is the buoyancy force? Alternatively, answer the fol- Challenge 669 s lowing question: why is it impossible for a submarine to move at relativistic speed?

In summary, length contraction can almost never be realistically observed for macroscopic bodies. However, it does play an important role for *images*.

Relativistic films – aberration and Doppler effect

We have encountered several ways in which observations change when an observer moves at high speed. First of all, Lorentz contraction and aberration lead to *distorted* images. Secondly, aberration increases the viewing angle beyond the roughly 180 degrees that humans are used to in everyday life. A relativistic observer who looks in the direction of motion sees light that is invisible for a resting observer, because for the latter, it comes from behind. Thirdly, the Doppler effect produces *colour-shifted* images. Fourthly, the rapid motion changes the *brightness* and *contrast* of the image: the so-called *searchlight effect*. Each of these changes depends on the direction of sight; they are shown in Figure 247.

Modern computers enable us to simulate the observations made by rapid observers with photographic quality, and even to produce simulated films.* The images of Figure 246 are particularly helpful in allowing us to understand image distortion. They show the viewing angle, the circle which distinguish objects in front of the observer from those behind the observer, the coordinates of the observer's feet and the point on the horizon toward which the observer is moving. Adding these markers in your head when watching other pictures or films may help you to understand more clearly what they show.

We note that the shape of the image seen by a moving observer is a *distorted* version of that seen by one at rest at the same point. A moving observer, however, does not see different things than a resting one at the same point. Indeed, light cones are independent of observer motion.

The Lorentz contraction is measurable; however, it cannot be photographed. This surprising distinction was discovered only in 1959. Measuring implies simultaneity at the object's position; photographing implies simultaneity at the observer's position. On a photograph, the Lorentz contraction is modified by the effects due to different light travel times from the different parts of an object; the result is a change in shape that is reminiscent of, but not exactly the same as, a rotation. The total deformation is an angle-dependent aberration. We discussed aberration at the beginning of this section. Aberration transforms circles into circles: such transformations are called *conformal*.

Ref. 344

Page 403

The images of Figure 248, produced by Daniel Weiskopf, also include the Doppler effect and the brightness changes. They show that these effects are at least as striking as the distortion due to aberration.

This leads to the *pearl necklace paradox*. If the relativistic motion transforms spheres into spheres, and rods into shorter rods, what happens to a pearl necklace moving along its own long axis? Does it get shorter?

described by an observer at rest with respect to both of them. (There is no connecting rope now.) Both cars contain the same amount of fuel. We easily deduce that the acceleration of the two twins stops, when the fuel runs out, at the same time in the frame of the outside observer. In addition, the distance between the cars has remained the same all along for the outside observer, and the two cars continue rolling with an identical constant velocity v, as long as friction is negligible. If we call the events at which the front car and back car engines switch off f and b, their time coordinates in the outside frame are related simply by $t_f = t_b$. By using the Lorentz transformations you can deduce for

Challenge 672 e

the frame of the freely rolling twins the relation

$$t_b = \gamma \Delta x \, v/c^2 + t_f \,, \tag{153}$$

which means that the front twin has aged *more* than the back twin! Thus, in accelerated systems, ageing is position-dependent.

For choosing a seat in a bus, though, this result does not help. It is true that the best seat in an accelerating bus is the back one, but in a decelerating bus it is the front one. At the end of a trip, the choice of seat does not matter.

Challenge 673 s

Is it correct to deduce that people on high mountains age faster than people in valleys, so that living in a valley helps postponing grey hair?

How fast can one walk?

To walk means to move the feet in such a way that at least one of them is on the ground at any time. This is one of the rules athletes have to follow in Olympic walking competitions; they are disqualified if they break it. A student athlete was thinking about the theoretical maximum speed he could achieve in the Olympics. The ideal would be that each foot accelerates instantly to (almost) the speed of light. The highest walking speed is achieved by taking the second foot off the ground at exactly the same instant at which the first is put down. By 'same instant', the student originally meant 'as seen by a competition judge at rest with respect to Earth'. The motion of the feet is shown in the left diagram of Figure 249; it gives a limit speed for walking of half the speed of light. But then the student noticed that a *moving* judge will see both feet off the ground and thus disqualify

Ref. 345

the athlete for running. To avoid disqualification by *any* judge, the second foot has to wait for a light signal from the first. The limit speed for Olympic walking is thus only one third of the speed of light.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

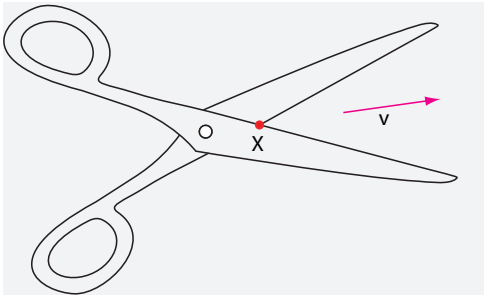

FIGURE 250 A simple example of motion that can be faster than light

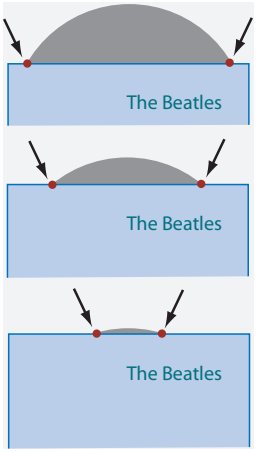

FIGURE 251 Another example of faster-than-light motion

Is the speed of shadow greater than the speed of light?

Actually, motion faster than light does exist and is even rather common. Special relativity only constrains the motion of mass and energy. However, non-material points or non-energy-transporting features and images *can* move faster than light. There are several simple examples. To be clear, we are not talking about *proper* velocity, which in these cases cannot be defined anyway. (Why?)

Page 425
Challenge 674 s

The following examples show speeds that are genuinely higher than the speed of light in vacuum.

Consider the point marked X in Figure 250, the point at which scissors cut paper. If the scissors are closed rapidly enough, the point moves faster than light. Similar examples can also be found in every window frame, and in fact in any device that has twisting parts.

Another example of superluminal motion is a music record – an old-fashioned LP – disappearing into its sleeve, as shown in Figure 251. The point where the edge of the record meets the edge of the sleeve can travel faster than light.

Another example suggests itself when we remember that we live on a spherical planet. Imagine you lie on the floor and stand up. Can you show that the initial speed with which the horizon moves away from you can be larger than that of light?

Challenge 675 s

Finally, a standard example is the motion of a spot of light produced by shining a laser beam onto the Moon. If the laser is moved, the spot can easily move faster than light. The same applies to the light spot on the screen of an oscilloscope when a signal of sufficiently high frequency is fed to the input.

All these are typical examples of the *speed of shadows*, sometimes also called the *speed of darkness*. Both shadows and darkness can indeed move faster than light. In fact, there is no limit to their speed. Can you find another example?

Challenge 676 s

In addition, there is an ever-increasing number of experimental set-ups in which the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

phase velocity or even the group velocity of light is higher than c. They regularly make headlines in the newspapers, usually along the lines of 'light moves faster than light'. We
Page 751 will discuss this surprising phenomenon in more detail later on. In fact, these cases can also be seen – with some imagination – as special cases of the 'speed of shadow' phenomenon.

For a different example, imagine we are standing at the exit of a tunnel of length l. We see a car, whose speed we know to be v, entering the other end of the tunnel and driving towards us. We know that it entered the tunnel because the car is no longer in the Sun or because its headlights were switched on at that moment. At what time t, after we see it entering the tunnel, does it drive past us? Simple reasoning shows that t is given by

$$t = l/v - l/c \,. \tag{154}$$

In other words, the approaching car seems to have a velocity v_{appr} of

$$v_{\text{appr}} = \frac{l}{t} = \frac{vc}{c - v} \,, \tag{155}$$

which is higher than c for any car velocity v higher than $c/2$. For cars this does not happen too often, but astronomers know a type of bright object in the sky called a *quasar* (a contraction of 'quasi-stellar object'), which sometimes emits high-speed gas jets. If the emission is in or near the direction of the Earth, its apparent speed – even the purely transverse component – is higher than c. Such situations are now regularly observed
Ref. 346 with telescopes.

Note that to a second observer at the *entrance* of the tunnel, the apparent speed of the car *moving away* is given by

$$v_{\text{leav}} = \frac{vc}{c + v} \,, \tag{156}$$

which is *never* higher than $c/2$. In other words, objects are never seen departing with more than half the speed of light.

The story has a final twist. We have just seen that motion faster than light can be observed in several ways. But could an *object* moving faster than light be observed at all? Surprisingly, it could be observed only in rather unusual ways. First of all, since such an imaginary object, usually called a *tachyon*, moves faster than light, we can never see it approaching. If it can be seen at all, a tachyon can only be seen departing. Seeing a tachyon would be similar to hearing a supersonic jet. Only *after* a tachyon has passed nearby, assuming that it is visible in daylight, could we notice it. We would first see a flash of light, corresponding to the bang of a plane passing with supersonic speed. Then we would see *two* images of the tachyon, appearing somewhere in space and departing in opposite directions, as can be deduced from Figure 252. Even if one of the two images were approaching us, it would be getting fainter and smaller. This is, to say the least, rather unusual behaviour. Moreover, if you wanted to look at a tachyon at night, illuminating it with a torch, you would have to turn your head in the direction opposite to the arm with the torch! This requirement also follows from the space-time diagram: can
Challenge 677 e you see why? Nobody has ever seen such phenomena. Tachyons, if they existed, would

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

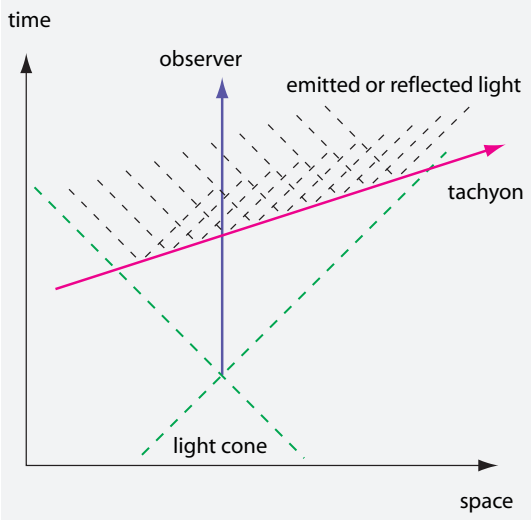

FIGURE 252 Hypothetical space-time diagram for tachyon observation

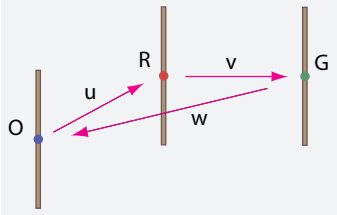

FIGURE 253 If O's stick is parallel to R's and R's is parallel to G's, then O's stick and G's stick are not

Ref. 347
Page 445

be strange objects: they would accelerate when they lose energy, a zero-energy tachyon would be the fastest of all, with infinite speed, and the direction of motion of a tachyon depends on the motion of the observer. No object with these properties has ever been observed. Worse, as we just saw, tachyons would seem to appear from nothing, defying laws of conservation; and note that, just as tachyons cannot be seen in the usual sense, they cannot be touched either, since both processes are due to electromagnetic interactions, as we will see later in our ascent of Motion Mountain. Tachyons therefore cannot be objects in the usual sense. In the quantum part of our adventure we will show that quantum theory actually *rules out* the existence of (real) tachyons. However, quantum theory also *requires* the existence of 'virtual' tachyons, as we will discover.

Parallel to parallel is not parallel – Thomas rotation

Relativity has strange consequences indeed. Any two observers can keep a stick parallel to the other's, even if they are in motion with respect to each other. But strangely, given a a chain of sticks for which any two adjacent ones are parallel, the first and the last sticks will *not* generally be parallel. In particular, they *never* will be if the motions of the various observers are in different directions, as is the case when the velocity vectors form a loop.

The simplest set-up is shown in Figure 253. In special relativity, a general concatena-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 348 tion of pure boosts does not give a pure boost, but a boost plus a rotation. As a result, the end points of chains of parallel sticks are usually not parallel.

An example of this effect appears in rotating motion. If we walk in a fast circle holding a stick, always keeping the stick parallel to the direction it had just before, at the end of the circle the stick will have an angle with respect to the original direction. Similarly, the axis of a rotating body circling a second body will *not* be pointing in the same direction after one turn. This effect is called *Thomas precession*, after Llewellyn Thomas, who discovered it in 1925, a full 20 years after the birth of special relativity. It had escaped the attention of dozens of other famous physicists. Thomas precession is important in the inner working of atoms; we will return to it in a later section of our adventure. These surprising phenomena are purely relativistic, and are thus measurable *only* in the case of speeds comparable to that of light.

A never-ending story – temperature and relativity

The literature on temperature is confusing. Albert Einstein and Wolfgang Pauli agreed on the following result: the temperature T seen by an observer moving with speed v is related to the temperature T_0 measured by the observer at rest with respect to the heat bath via

$$T = T_0\sqrt{1 - v^2/c^2}\,. \tag{157}$$

A moving observer thus always measures lower values than a resting one.

In 1908, Max Planck used this expression, together with the corresponding transformation for heat, to deduce that the entropy is invariant under Lorentz transformations. Being the discoverer of the Boltzmann constant k, Planck proved in this way that the constant is a relativistic invariant.

Not all researchers agree on the expression. Others maintain that T and T_0 should be interchanged in the temperature transformation. Also, powers other than the simple
Ref. 349 square root have been proposed. The origin of these discrepancies is simple: temperature is only defined for equilibrium situations, i.e., for baths. But a bath for one observer is not a bath for the other. For low speeds, a moving observer sees a situation that is *almost* a heat bath; but at higher speeds the issue becomes tricky. Temperature is deduced from the speed of matter particles, such as atoms or molecules. For moving observers, there is no good way to measure temperature. The naively measured temperature value even depends on the energy range of matter particles that is measured! In short, thermal equilibrium is not an observer-invariant concept. Therefore, *no* temperature transformation formula is correct. (With certain additional assumptions, Planck's expression does seem to hold, however.) In fact, there are not even any experimental observations that would allow such a formula to be checked. Realizing such a measurement is a challenge for future experimenters – but not for relativity itself.

RELATIVISTIC MECHANICS

Because the speed of light is constant and velocities do not add up, we need to rethink the definitions of mass, momentum and energy. We thus need to recreate a theory of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

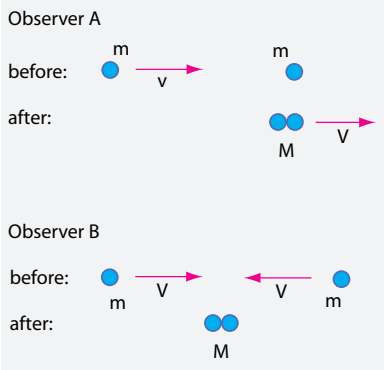

FIGURE 254 An inelastic collision of two identical particles seen from two different inertial frames of reference

mechanics from scratch.

Mass in relativity

Page 91 In Galilean physics, the mass ratio between two bodies was defined using collisions; it was given by the negative inverse of the velocity change ratio

$$\frac{m_2}{m_1} = -\frac{\Delta v_1}{\Delta v_2} \,. \tag{158}$$

However, experiments show that the expression must be different for speeds near that of light. In fact, experiments are not needed: thinking alone can show this. Can you do so? Challenge 678 ny

There is only one solution to this problem. The two Galilean conservation theorems $\sum_i m_i \boldsymbol{v}_i = \text{const}$ for momentum and $\sum_i m_i = \text{const}$ for mass have to be changed into Ref. 350

$$\sum_i \gamma_i m_i \boldsymbol{v}_i = \text{const} \tag{159}$$

and

$$\sum_i \gamma_i m_i = \text{const} \,. \tag{160}$$

These expressions, which will remain valid throughout the rest of our ascent of Motion Mountain, imply, among other things, that teleportation is *not* possible in nature. (Can you confirm this?) Obviously, in order to recover Galilean physics, the relativistic correction (factors) γ_i have to be almost equal to 1 for everyday velocities, that is, for velocities nowhere near the speed of light. Challenge 679 s

Even if we do not know the value of the relativistic correction factor, we can deduce it from the collision shown in Figure 254.

In the first frame of reference (A) we have $\gamma_v mv = \gamma_V MV$ and $\gamma_v m + m = \gamma_V M$. From the observations of the second frame of reference (B) we deduce that V composed with V gives v, in other words, that Challenge 680 e

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$v = \frac{2V}{1 + V^2/c^2} \,. \tag{161}$$

When these equations are combined, the relativistic correction γ is found to depend on the magnitude of the velocity v through

$$\gamma_v = \frac{1}{\sqrt{1 - v^2/c^2}} \,. \tag{162}$$

With this expression, and a generalization of the situation of Galilean physics, the *mass* ratio between two colliding particles is defined as the ratio

$$\frac{m_1}{m_2} = -\frac{\Delta(\gamma_2 v_2)}{\Delta(\gamma_1 v_1)} \,. \tag{163}$$

(We do not give here the generalized mass definition, mentioned in the chapter on Galilean mechanics, that is based on acceleration ratios, because it contains some subtleties, which we will discover shortly.) The correction factors γ_i ensure that the mass defined by this equation is the same as the one defined in Galilean mechanics, and that it is the same for all types of collision a body may have.* In this way, mass remains a quantity characterizing the difficulty of accelerating a body, and it can still be used for *systems* of bodies as well.

Page 94

Following the example of Galilean physics, we call the quantity

$$\boldsymbol{p} = \gamma m \boldsymbol{v} \tag{164}$$

the (*linear*) *relativistic* (*three-*) *momentum* of a particle. Again, the total momentum is a *conserved* quantity for any system not subjected to external influences, and this conservation is a direct consequence of the way mass is defined.

For low speeds, or $\gamma \approx 1$, relativistic momentum is the same as that of Galilean physics, and is proportional to velocity. But for high speeds, momentum increases faster than velocity, tending to infinity when approaching light speed.

Why relativistic snooker is more difficult

There is a well-known property of collisions between a moving sphere or particle and a resting one of the *same mass* that is important when playing snooker, pool or billiards. After such a collision, the two spheres will depart at a *right angle* from each other, as shown in Figure 255.

However, experiments show that the right angle rule does *not* apply to relativistic collisions. Indeed, using the conservation of momentum and a bit of dexterity you can calculate that

Challenge 682 e

$$\tan\theta \tan\varphi = \frac{2}{\gamma + 1} \,, \tag{165}$$

Challenge 681 e

* The results below also show that $\gamma = 1 + T/mc^2$, where T is the kinetic energy of a particle.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

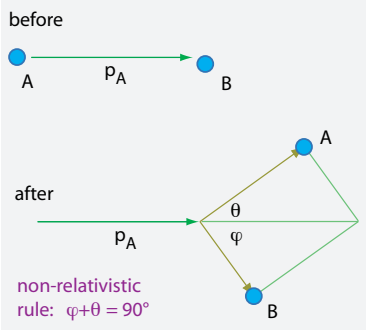

FIGURE 255 A useful rule for playing non-relativistic snooker

where the angles are defined in Figure 256. It follows that the sum $\varphi + \theta$ is *smaller* than a right angle in the relativistic case. Relativistic speeds thus completely change the game of snooker. Indeed, every accelerator physicist knows this: for electrons or protons, these angles can easily be deduced from photographs taken in cloud chambers, which show the tracks left by particles when they move through them. All such photographs confirm the above expression. In fact, the shapes of detectors are chosen according to expression (165), as sketched in Figure 256. If the formula – and relativity – were wrong, most of these detectors would not work, as they would miss most of the particles after the collision. If relativity were wrong, detectors would have to be much larger. In fact, these experiments also prove the formula for the composition of velocities. Can you show this?

Ref. 317

Challenge 683 ny

Mass is concentrated energy

Let us go back to the collinear and inelastic collision of Figure 254. What is the mass M of the final system? Calculation shows that

Challenge 684 s

$$M/m = \sqrt{2(1+\gamma_v)} > 2\,. \tag{166}$$

In other words, the mass of the final system is *larger* than the sum of the two original masses m. In contrast to Galilean mechanics, the sum of all masses in a system is *not* a conserved quantity. Only the sum $\sum_i \gamma_i m_i$ of the corrected masses is conserved.

Relativity provides the solution to this puzzle. Everything falls into place if, for the *energy* E of an object of mass m and velocity v, we use the expression

$$E = \gamma mc^2 = \frac{mc^2}{\sqrt{1 - v^2/c^2}}\,, \tag{167}$$

applying it both to the total system and to each component. The conservation of the corrected mass can then be read as the conservation of energy, simply without the factor c^2. In the example of the two identical masses sticking to each other, the two particles are thus each described by mass and energy, and the resulting system has an energy E given by the sum of the energies of the two particles. In particular, it follows that the energy

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

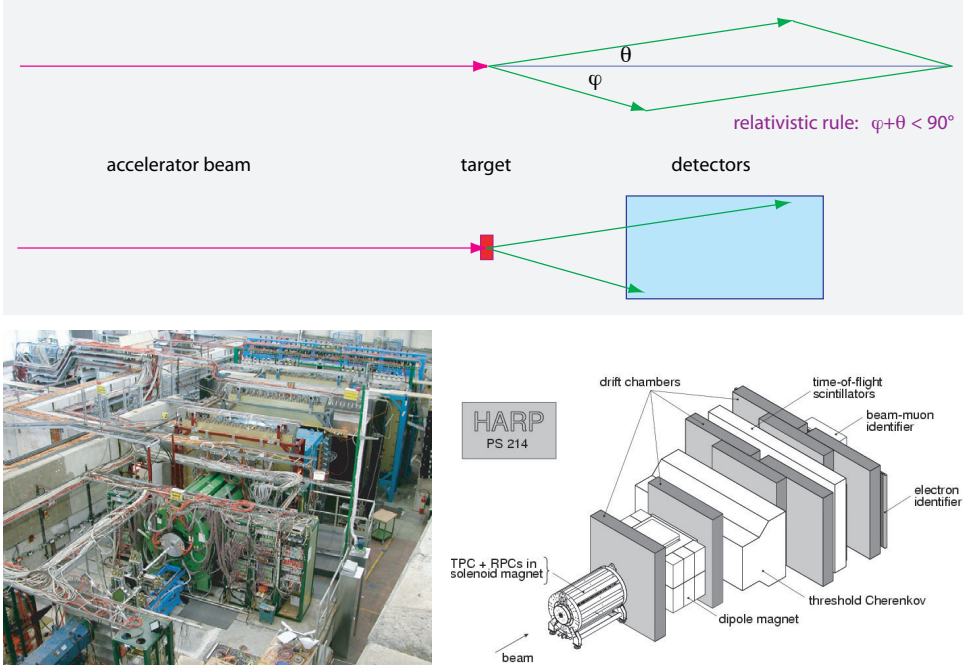

FIGURE 256 The dimensions of detectors for particle accelerators with single beams are based on the relativistic snooker angle rule – as an example, the HARP experiment at CERN (© CERN)

E_0 of a body *at rest* and its mass m are related by

$$E_0 = mc^2 \,, \tag{168}$$

which is perhaps the most beautiful and famous discovery of modern physics. Since c^2 is so large, we can say that *mass is concentrated energy*. In other words, special relativity says that every mass has energy, and that every form of energy in a system has mass. Increasing the energy of a system increases its mass, and decreasing the energy content decreases the mass. In short, if a bomb explodes inside a closed box, the mass, weight and momentum of the box are the same before and after the explosion, but the combined mass of the debris inside the box will be *smaller* than before. All bombs – not only nuclear ones – thus take their energy from a reduction in mass. In addition, every action of a system – such as a caress, a smile or a look – takes its energy from a reduction in mass.

The kinetic energy T is thus given by

$$T = \gamma mc^2 - mc^2 = \frac{1}{2}mv^2 + \frac{1\cdot 3}{2\cdot 4}m\frac{v^4}{c^2} + \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}m\frac{v^6}{c^4} + \ldots \tag{169}$$

Challenge 685 e (using the binomial theorem) which reduces to the Galilean value only for low speeds.

The mass–energy equivalence $E = \gamma mc^2$ implies that taking *any* energy from matter results in a mass decrease. When a person plays the piano, thinks or runs, its mass de-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

creases. When a cup of tea cools down or when a star shines, its mass decreases. The mass–energy equivalence pervades all of nature.

By the way, we should be careful to distinguish the transformation of *mass* into energy from the transformation of *matter* into energy. The latter is much more rare. Can you give some examples? Challenge 686 s

The mass–energy relation (167) means the death of many science fiction fantasies. It implies that there are *no* undiscovered sources of energy on or near Earth. If such sources existed, they would be measurable through their mass. Many experiments have looked for, and are still looking for, such effects with a negative result. There is no free energy in nature.*

The mass–energy relation $m = E_0/c^2$ also implies that one needs about 90 thousand million kJ (or 21 thousand million kcal) to increase one's weight by one single gram. Of course, dieticians have slightly different opinions on this matter! In fact, humans do get their everyday energy from the material they eat, drink and breathe by reducing its combined mass before expelling it again. However, this *chemical mass defect* appearing when fuel is burned cannot yet be measured by weighing the materials before and after the reaction: the difference is too small, because of the large conversion factor involved. Indeed, for any chemical reaction, bond energies are about 1 aJ (6 eV) per bond; this gives a weight change of the order of one part in 10^{10}, too small to be measured by weighing people or determining mass differences between food and excrement. Therefore, for everyday chemical processes mass can be taken to be constant, in accordance with Galilean physics.

The mass–energy equivalence has been confirmed by all experiments performed so far. The measurement is simplest for the *nuclear mass defect*. The most precise experiment, from 2005, confirmed the mass–energy relation to more than 6 digits, by comparing the masses difference of nuclei before and after neutron capture on one hand, and emitted gamma ray energy on the other hand. Ref. 351

Modern methods of mass measurement of single molecules have even made it possible to measure the *chemical* mass defect, by comparing the mass of a single molecule with that of its constituent atoms. David Pritchard's group has developed so-called *Penning traps*, which allow masses to be determined from the measurement of frequencies; the attainable precision of these cyclotron resonance experiments is sufficient to confirm $\Delta E_0 = \Delta m c^2$ for chemical bonds. In the future, increased precision will even allow bond energies to be determined in this way with precision. Since binding energy is often radiated as light, we can say that these modern techniques make it possible to *weigh* light. Ref. 352

Thinking about light and its mass was the basis for Einstein's first derivation of the mass–energy relation. When an object emits two equal light beams in opposite directions, its energy decreases by the emitted amount. Since the two light beams are equal in energy and momentum, the body does not move. If we describe the same situation from the viewpoint of a moving observer, we see again that the *rest energy* of the object is Challenge 687 e

$$E_0 = mc^2 \,. \tag{170}$$

* There may be two extremely diluted, yet undiscovered, form of energy, called *dark matter* and (confusingly) *dark energy*, scattered throughout the universe. They are deduced from (quite difficult) mass measurements. The issue has not yet been finally resolved. Page 568

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In summary, all physical processes, including collisions, need relativistic treatment whenever the energy involved is a sizeable fraction of the rest energy.

Every energy increase produces a mass increase. Therefore also heating a body makes it heavier. However, this effect is so small that nobody has measured it up to this day. It is a challenge for experiments of the future to do this one day.

How are energy and momentum related? The definitions of momentum (164) and
Challenge 688 e energy (167) lead to two basic relations. First of all, their magnitudes are related by

$$m^2c^4 = E^2 - p^2c^2 \tag{171}$$

for all relativistic systems, be they objects or, as we will see below, radiation. For the momentum *vector* we get the other important relation

$$\boldsymbol{p} = \frac{E}{c^2}\boldsymbol{v}\,, \tag{172}$$

Challenge 689 e which is equally valid for *any* type of moving energy, be it an object or a beam or a pulse of radiation.* We will use both relations often in the rest of our ascent of Motion Mountain, including the following discussion.

Collisions, virtual objects and tachyons

We have just seen that in relativistic collisions the conservation of total energy and momentum are intrinsic consequences of the definition of mass. Let us now have a look at collisions in more detail, using these new concepts. A *collision* is a process, i.e., a series of events, for which

— the total momentum before the interaction and after the interaction is the same;
— the momentum is exchanged in a small region of space-time;
— for small velocities, the Galilean description is valid.

In everyday life an *impact*, i.e., a short-distance interaction, is the event at which both objects change momentum. But the two colliding objects are located at *different* points
Ref. 353 when this happens. A collision is therefore described by a space-time diagram such as the left-hand one in Figure 257, reminiscent of the Orion constellation. It is easy to check that
Challenge 690 e the process described by such a diagram is a collision according to the above definition.

The right-hand side of Figure 257 shows the same process seen from another, Greek, frame of reference. The Greek observer says that the first object has changed its momentum *before* the second one. That would mean that there is a short interval when momentum and energy are *not* conserved!

The only way to make sense of the situation is to assume that there is an exchange of a third object, drawn with a dotted line. Let us find out what the properties of this object are. If we give numerical subscripts to the masses, energies and momenta of the
Challenge 691 e two bodies, and give them a prime after the collision, the unknown mass m obeys

* In 4-vector notation, we can write $\boldsymbol{v}/c = \boldsymbol{p}/P_0$, where $P_0 = E/c$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

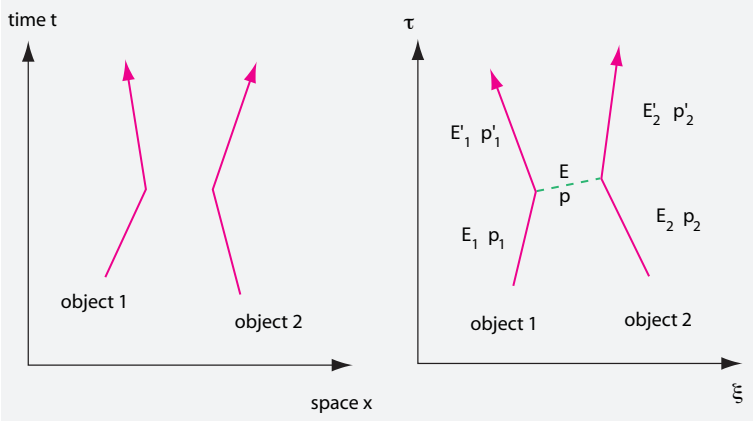

FIGURE 257 Space-time diagram of a collision for two observers

$$m^2c^4 = (E_1 - E_1')^2 - (p_1 - p_1')^2c^2 = 2m_1^2c^4 - 2E_1E_1'\left(\frac{1 - v_1v_1'}{c^2}\right) < 0\ . \qquad (173)$$

This is a strange result, because it means that the unknown mass is an *imaginary* number![*] On top of that, we also see directly from the second graph that the exchanged object moves faster than light. It is a *tachyon*, from the Greek ταχύς 'rapid'. In other words, collisions involve motion that is faster than light! We will see later that collisions are indeed the *only* processes where tachyons play a role in nature. Since the exchanged objects appear only during collisions, never on their own, they are called *virtual* objects, to distinguish them from the usual, *real* objects, which can move freely without restriction.[**] We will study their properties later on, when we come to discuss quantum theory.

In nature, a tachyon is always a virtual object. Real objects are always *bradyons* – from the Greek βραδύς 'slow' – or objects moving slower than light. Note that tachyons, despite their high velocity, do not allow the transport of energy faster than light; and that they do not violate causality if and only if they are emitted or absorbed with equal probability. Challenge 692 ny Can you confirm all this?

When we study quantum theory, we will also discover that a general contact interaction between objects is described not by the exchange of a *single* virtual object, but by a continuous *stream* of virtual particles. For standard collisions of everyday objects, the interaction turns out to be electromagnetic. In this case, the exchanged particles are virtual photons. In other words, when one hand touches another, when it pushes a stone, or when a mountain supports the trees on it, streams of virtual photons are continuously exchanged. Page 1012

[*] It is usual to change the mass–energy and mass–momentum relation of tachyons to $E = \pm mc^2/\sqrt{v^2/c^2 - 1}$ and $p = \pm mv/\sqrt{v^2/c^2 - 1}$; this amounts to a redefinition of m. After the redefinition, tachyons have *real* mass. The energy and momentum relations show that tachyons lose energy and momentum when they get faster. (Provocatively, a single tachyon in a box could provide us with all the energy we need.) Both signs for the energy and momentum relations must be retained, because otherwise the equivalence of all inertial observers would not be generated. Tachyons thus do not have a minimum energy or a minimum

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

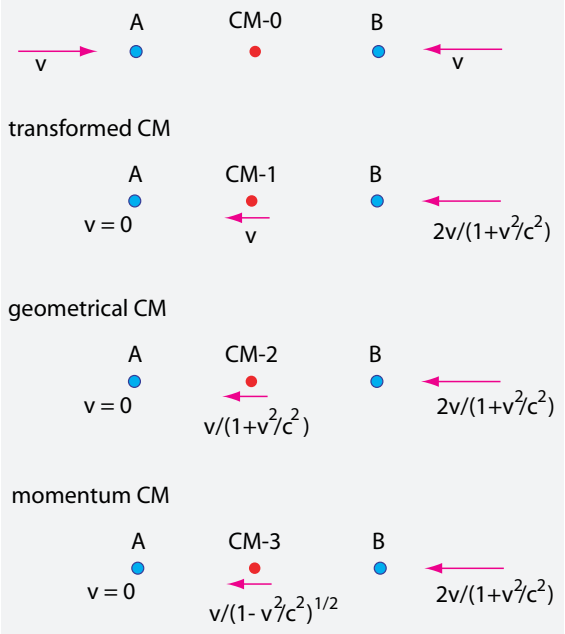

FIGURE 258 There is no consistent way to define a relativistic centre of mass

There is an additional secret hidden in collisions. In the right-hand side of Figure 257, the tachyon is emitted by the first object and absorbed by the second one. However, it is easy to imagine an observer for which the opposite happens. In short, the direction of travel of a tachyon depends on the observer! In fact, this is a hint about *antimatter*. In space-time diagrams, matter and antimatter travel in opposite directions. Also the connection between relativity and antimatter will become more apparent in quantum theory.

Challenge 693 s

Page 1049

Systems of particles – no centre of mass

Relativity also forces us to eliminate the cherished concept of *centre of mass*. We can see this already in the simplest example possible: that of two equal objects colliding.

Figure 258 shows that from the viewpoint in which one of two colliding particles is at rest, there are at least three different ways to define the centre of mass. In other words, the centre of mass is not an observer-invariant concept. We can deduce from the figure that the concept only makes sense for systems whose components move with *small* velocities relative to each other. For more general systems, centre of mass is not uniquely definable. Will this hinder us in our ascent? No. We are more interested in the motion of single particles than that of composite objects or systems.

Ref. 354

momentum.

** More precisely, a virtual particle does not obey the relation $m^2c^4 = E^2 - p^2c^2$, valid for real particles.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Why is most motion so slow?

For most everyday systems, the time intervals measured by two different observers are practically equal; only at large relative speeds, typically at more than a few per cent of the speed of light, is there a noticeable difference. Most such situations are microscopic. We have already mentioned the electrons inside a television tube or inside a particle accelerator. The particles making up cosmic radiation are another example: their high energy has produced many of the mutations that are the basis of evolution of animals and plants on this planet. Later we will discover that the particles involved in radioactivity are also relativistic.

But why don't we observe any rapid *macroscopic* bodies? Moving bodies, including observers, with relativistic velocities have a property not found in everyday life: when they are involved in a collision, part of their energy is converted into new matter via $E = \gamma mc^2$. In the history of the universe this has happened so many times that practically all the bodies still in relativistic motion are microscopic particles.

A second reason for the disappearance of rapid relative motion is radiation damping. Challenge 694 s Can you imagine what happens to charges during collisions, or in a bath of light?

In short, almost all matter in the universe moves with small velocity relative to other matter. The few known counter-examples are either very old, such as the quasar jets mentioned above, or stop after a short time. The huge energies necessary for macroscopic relativistic motion are still found in supernova explosions, but they cease to exist after only a few weeks. In summary, the universe is mainly filled with slow motion because it Page 577 is *old*. We will determine its age shortly.

The history of the mass–energy equivalence formula of De Pretto and Einstein

Albert Einstein took several months after his first paper on special relativity to deduce the expression

$$E = \gamma mc^2 \tag{174}$$

which is often called the most famous formula of physics. He published it in a second, Ref. 306 separate paper towards the end of 1905. Arguably, the formula could have been discovered thirty years earlier, from the theory of electromagnetism.

In fact, at least one person did deduce the result before Einstein. In 1903 and 1904, *before* Einstein's first relativity paper, a little-known Italian engineer, Olinto De Pretto, was the first to calculate, discuss and publish the formula $E = mc^2$.* It might well be that Einstein got the idea for the formula from De Pretto, possibly through Einstein's friend Michele Besso or other Italian-speaking friends he met when he visited his parents, who were living in Italy at the time. Of course, the value of Einstein's efforts is not diminished by this.

Ref. 355 In fact, a similar formula had also been deduced in 1904 by Friedrich Hasenöhrl and published again in Annalen der Physik in 1905, before Einstein, though with an incorrect numerical prefactor, due to a calculation mistake. The formula $E = mc^2$ is also part of

* Umberto Bartocci, mathematics professor of the University of Perugia in Italy, published the details of this surprising story in several papers. The full account is found in his book Umberto Bartocci, *Albert Einstein e Olinto De Pretto: la vera storia della formula più famosa del mondo*, Ultreja, 1998.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

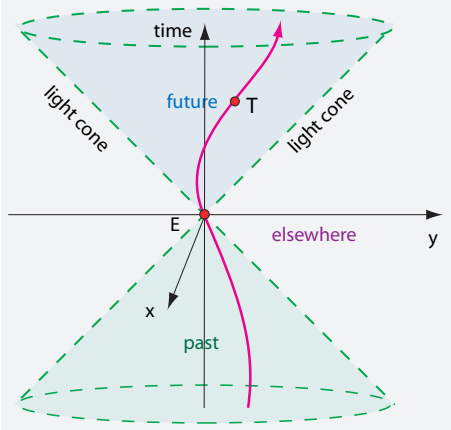

FIGURE 259 The space-time diagram of a moving object T

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

several expressions in two publications in 1900 by Henri Poincaré. Also Paul Langevin knew it, and Einstein said of him that he would surely have discovered the theory of special relativity had it not been known before. The real hero in the story might well be Tolver Preston, who discussed the equivalence of mass and energy already in 1875, in his book *Physics of the Ether*. The mass–energy equivalence was thus indeed floating in the air, only waiting to be discovered.

In the 1970s, there a similar story occurred: a simple relation between the gravitational acceleration and the temperature of the vacuum was discovered. The result had been waiting to be discovered for over 50 years. Indeed, a number of similar, anterior results were found in the libraries. Could other simple relations be hidden in modern physics waiting to be found?

Page 1207

Challenge 695 s

4-VECTORS

To describe motion consistently for *all* observers, we have to introduce some new quantities. First of all, motion of particles is seen as a sequence of events. To describe events with precision, we use event coordinates, also called *4-coordinates*. These are written as

$$\boldsymbol{X} = (ct, \boldsymbol{x}) = (ct, x, y, z) = X^i \,. \tag{175}$$

In this way, an event is a point in four-dimensional space-time, and is described by four coordinates. The coordinates are called the zeroth, namely time $X^0 = ct$, the first, usually called $X^1 = x$, the second, $X^2 = y$, and the third, $X^3 = z$. One can then define a *distance d* between events as the length of the difference vector. In fact, one usually uses the square of the length, to avoid those unwieldy square roots. In special relativity, the magnitude ('squared length') of a vector is always defined through

$$\boldsymbol{X}\boldsymbol{X} = {X_0}^2 - {X_1}^2 - {X_2}^2 - {X_3}^2 = ct^2 - x^2 - y^2 - z^2 = X_a X^a = \eta_{ab} X^a X^b = \eta^{ab} X_a X_b \,. \tag{176}$$

In this equation we have introduced for the first time two notations that are useful in relativity. First of all, we automatically sum over repeated indices. Thus, $X_a X^a$ means the sum of all products $X_a X^a$ as a ranges over all indices. Secondly, for every 4-vector $\boldsymbol{X}$ we distinguish two ways to write the coordinates, namely coordinates with superscripts and coordinates with subscripts. (In three dimensions, we only use subscripts.) They are related by the following general relation

$$X_a = \eta_{ab} X^b = (ct, -x, -y, -z) \,, \tag{177}$$

where we have introduced the so-called *metric* η^{ab}, an abbreviation of the matrix*

$$\eta^{ab} = \eta_{ab} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} . \tag{178}$$

Don't panic: this is all, and it won't get more difficult! (A generalization of this matrix is used in general relativity.) We now go back to physics.

The magnitude of a position or distance vector, also called the space-time *interval*, is essentially the proper time times c. The *proper time* is the time shown by a clock moving in a straight line and with constant velocity from the starting point to the end point in space-time. The difference from the usual 3-vectors is that the magnitude of the interval can be positive, negative or even zero. For example, if the start and end points in space-time require motion with the speed of light, the proper time is zero (this is required for null vectors). If the motion is slower than the speed of light, the squared proper time is positive and the distance is timelike. For negative intervals and thus imaginary proper times, the distance is spacelike.** A simplified overview is given by Figure 259.

Page 424

Now we are ready to calculate and measure motion in four dimensions. The measurements are based on one central idea. We cannot define the velocity of a particle as the derivative of its coordinates with respect to time, since time and temporal sequences depend on the observer. The solution is to define all observables with respect to the just-mentioned *proper time* τ, which is defined as the time shown by a clock attached to the object. In relativity, motion and change are always measured with respect to clocks attached to the moving system. In particular, the *relativistic velocity* or *4-velocity* $\boldsymbol{U}$ of a body is thus defined as the rate of change of the event coordinates or *4-coordinates* $\boldsymbol{X} = (ct, \boldsymbol{x})$ with respect to proper time, i.e., as

$$\boldsymbol{U} = \frac{\mathrm{d}\boldsymbol{X}}{\mathrm{d}\tau} \,. \tag{179}$$

The coordinates $\boldsymbol{X}$ are measured in the coordinate system defined by the inertial observer chosen. The value of the velocity $\boldsymbol{U}$ depends on the observer or coordinate system used;

* Note that 30 % of all physics textbooks use the negative of η as the metric, the so-called *spacelike convention*, and thus have opposite signs in this definition. In this text, as in 70 % of all physics texts, we use the *timelike convention*.

** In the latter case, the negative of the magnitude, which is a positive number, is called the squared *proper distance*. The proper distance is the length measured by an odometer as the object moves along.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

so the velocity depends on the observer, as it does in everyday life. Using $\mathrm{d}t = \gamma\,\mathrm{d}\tau$ and thus

$$\frac{\mathrm{d}x}{\mathrm{d}\tau} = \frac{\mathrm{d}x}{\mathrm{d}t}\frac{\mathrm{d}t}{\mathrm{d}\tau} = \gamma\frac{\mathrm{d}x}{\mathrm{d}t} \quad \text{, where as usual} \quad \gamma = \frac{1}{\sqrt{1 - v^2/c^2}}\,, \tag{180}$$

we get the relation with the 3-velocity $\boldsymbol{v} = \mathrm{d}\boldsymbol{x}/\mathrm{d}t$:

$$u^0 = \gamma c\,,\ u^i = \gamma v_i \quad \text{or} \quad \boldsymbol{U} = (\gamma c, \gamma \boldsymbol{v})\,. \tag{181}$$

For small velocities we have $\gamma \approx 1$, and then the last three components of the 4-velocity are those of the usual, Galilean 3-velocity. For the magnitude of the 4-velocity $\boldsymbol{U}$ we find $\boldsymbol{U}\boldsymbol{U} = U_a U^a = \eta_{ab} U^a U^b = c^2$, which is therefore independent of the magnitude of the 3-velocity $\boldsymbol{v}$ and makes it a timelike vector, i.e., a vector *inside* the light cone.*

Note that the magnitude of a 4-vector can be zero even though all its components are different from zero. Such a vector is called *null*. Which motions have a null velocity vector? Challenge 697 s

Similarly, the *relativistic acceleration* or *4-acceleration* $\boldsymbol{B}$ of a body is defined as

$$\boldsymbol{B} = \mathrm{d}\boldsymbol{U}/\mathrm{d}\tau = \mathrm{d}^2\boldsymbol{X}/\mathrm{d}\tau^2\,. \tag{183}$$

Using $\mathrm{d}\gamma/\mathrm{d}\tau = \gamma\mathrm{d}\gamma/\mathrm{d}t = \gamma^4\boldsymbol{v}a/c^2$, we get the following relations between the four components of $\boldsymbol{B}$ and the 3-acceleration $\boldsymbol{a} = \mathrm{d}\boldsymbol{v}/\mathrm{d}t$: Ref. 356

$$B^0 = \gamma^4\frac{\boldsymbol{v}a}{c} \quad , \quad B^i = \gamma^2 a_i + \gamma^4\frac{(\boldsymbol{v}a)v_i}{c^2}\,. \tag{184}$$

The magnitude B of the 4-acceleration is easily found via $\boldsymbol{B}B = \eta_{cd}B^cB^d = -\gamma^4(a^2 + \gamma^2(\boldsymbol{v}\boldsymbol{a})^2/c^2) = -\gamma^6(a^2 - (\boldsymbol{v}\times\boldsymbol{a})^2/c^2)$. Note that it does depend on the value of the 3-acceleration $\boldsymbol{a}$. The magnitude of the 4-acceleration is also called the *proper* acceleration because $\boldsymbol{B}^2 = -a^2$ if $v = 0$. (What is the connection between 4-acceleration and 3-acceleration for an observer moving with the same speed as the object?) Challenge 698 s We note that 4-acceleration lies *outside* the light cone, i.e., that it is a spacelike vector, and that $\boldsymbol{B}\boldsymbol{U} = \eta_{cd}B^cU^d = 0$, which means that the 4-acceleration is always perpendicular to the

* In general, a *4-vector* is defined as a quantity (h_0, h_1, h_2, h_3), which transforms as

$$\begin{aligned} h'_0 &= \gamma_V(h_0 - h_1 V/c) \\ h'_1 &= \gamma_V(h_1 - h_0 V/c) \\ h'_2 &= h_2 \\ h'_3 &= h_3 \end{aligned} \tag{182}$$

when changing from one inertial observer to another moving with a relative velocity V in the x direction; the corresponding generalizations for the other coordinates are understood. This relation allows one to deduce the transformation laws for any 3-vector. Can you deduce the velocity composition formula (142) from this definition, applying it to 4-velocity? Challenge 696 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

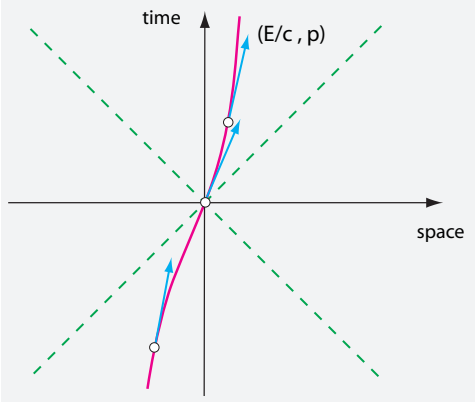

FIGURE 260 Energy–momentum is tangent to the world line

4-velocity.* We also note that accelerations, in contrast to velocities, cannot be called relativistic: the difference between b_i and a_i, or between their two magnitudes, does not depend on the value of a_i, but only on the value of the speed v. In other words, accelerations require relativistic treatment only when the involved velocities are relativistic. If the velocities involved are low, even the highest accelerations can be treated with Galilean methods.

When the acceleration $\boldsymbol{a}$ is parallel to the velocity $\boldsymbol{v}$, we get $B = \gamma^3 a$; when $\boldsymbol{a}$ is perpendicular to $\boldsymbol{v}$, as in circular motion, we get $B = \gamma^2 a$. We will use this result below.

Page 459

4-MOMENTUM

To describe motion, we also need the concept of momentum. The *4-momentum* is defined as

$$\boldsymbol{P} = m\boldsymbol{U} \tag{187}$$

and is therefore related to the 3-momentum $\boldsymbol{p}$ by

$$\boldsymbol{P} = (\gamma mc, \gamma m\boldsymbol{v}) = (E/c, \boldsymbol{p}) \,. \tag{188}$$

For this reason 4-momentum is also called the *energy–momentum 4-vector*. In short, *the 4-momentum of a body is given by mass times 4-displacement per proper time*. This is the simplest possible definition of momentum and energy. The concept was introduced by Max Planck in 1906. The energy–momentum 4-vector, also called *momenergy*, like the

* Similarly, the *relativistic jerk* or *4-jerk* $\boldsymbol{J}$ of a body is defined as

$$\boldsymbol{J} = \mathrm{d}\boldsymbol{B}/\mathrm{d}\tau = \mathrm{d}^2\boldsymbol{U}/\mathrm{d}\tau^2 \,. \tag{185}$$

Challenge 699 e For the relation with the 3-jerk $\boldsymbol{j} = \mathrm{d}\boldsymbol{a}/\mathrm{d}t$ we then get

$$\boldsymbol{J} = (J^0, J^i) = \left(\frac{\gamma^5}{c}(\boldsymbol{jv} + a^2 + 4\gamma^2 \frac{(\boldsymbol{va})^2}{c^2}) \,,\, \gamma^3 j_i + \frac{\gamma^5}{c^2}((\boldsymbol{jv})v_i + a^2 v_i + 4\gamma^2 \frac{(\boldsymbol{va})^2 v_i}{c^2} + 3(\boldsymbol{va})a_i) \right) \tag{186}$$

Challenge 700 ny which we will use later on. Surprisingly, $\boldsymbol{J}$ does not vanish when $\boldsymbol{j}$ vanishes. Why not?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

4-velocity, is *tangent* to the world line of a particle. This connection, shown in Figure 260, follows directly from the definition, since

$$(E/c, \boldsymbol{p}) = (\gamma mc, \gamma m\boldsymbol{v}) = m(\gamma c, \gamma \boldsymbol{v}) = m(\mathrm{d}t/\mathrm{d}\tau, \mathrm{d}\boldsymbol{x}/\mathrm{d}\tau) \,. \tag{189}$$

The (square of the) length of momenergy, namely $\boldsymbol{PP} = \eta_{ab} P^a P^b$, is by definition the same for all inertial observers; it is found to be

$$E^2/c^2 - p^2 = m^2 c^2 \,, \tag{190}$$

thus confirming a result given above. We have already mentioned that energies or situations are called *relativistic* if the kinetic energy $T = E - E_0$ is not negligible when compared to the rest energy $E_0 = mc^2$. A particle whose kinetic energy is much higher than its rest mass is called *ultrarelativistic*. Particles in accelerators or in cosmic rays fall into this category. (What is their energy–momentum relation?) Challenge 701 s

In contrast to Galilean mechanics, relativity implies an absolute zero for the energy. One cannot extract more energy than mc^2 from a system of mass m. In particular, a zero value for potential energy is fixed in this way. In short, relativity shows that energy is bounded from below.

Note that by the term 'mass' m we always mean what is sometimes called the *rest mass*. This name derives from the bad habit of many science fiction and secondary-school books of calling the product γm the *relativistic mass*. Workers in the field usually (but not unanimously) reject this concept, as did Einstein himself, and they also reject the often-heard expression that '(relativistic) mass increases with velocity'. Relativistic mass and energy would then be two words for the same concept: this way to talk is at the level of the tabloid press. Ref. 357

Not all Galilean energy contributes to mass. Potential energy in an outside field does not. Relativity forces us into precise energy bookkeeping. 'Potential energy' in relativity is an abbreviation for 'energy reduction of the outside field'.

Can you show that for two particles with momenta P_1 and P_2, one has $P_1P_2 = m_1E_2 = M_2E_1 = c^2\gamma v_{12} m_1 m_2$, where v_{12} is their relative velocity? Challenge 702 s

4-FORCE

The 4-force $\boldsymbol{K}$ is defined as

$$\boldsymbol{K} = \mathrm{d}\boldsymbol{P}/\mathrm{d}\tau = m\boldsymbol{B} \,. \tag{191}$$

Therefore force remains equal to mass times acceleration in relativity. From the definition of $\boldsymbol{K}$ we deduce the relation with 3-force $\boldsymbol{F} = \mathrm{d}\boldsymbol{p}/\mathrm{d}t = m\mathrm{d}(\gamma\boldsymbol{v})/\mathrm{d}t$, namely* Ref. 356, Ref. 358

$$\boldsymbol{K} = (K^0, K^i) = \left(\gamma^4 m\boldsymbol{v}\boldsymbol{a}/c, \gamma^2 m a_i + \gamma^4 v_i \frac{m\boldsymbol{v}\boldsymbol{a}}{c^2}\right) = \left(\frac{\gamma}{c}\frac{\mathrm{d}E}{\mathrm{d}t}, \gamma\frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}t}\right) = \left(\gamma\frac{\boldsymbol{F}v}{c}, \gamma\boldsymbol{F}\right) \,. \tag{192}$$

* Some authors define 3-force as $\mathrm{d}\boldsymbol{p}/\mathrm{d}\tau$; then $\boldsymbol{K}$ looks slightly different. In any case, it is important to note that in relativity, 3-force $\boldsymbol{F} = \mathrm{d}\boldsymbol{p}/\mathrm{d}t$ is indeed proportional to 3-acceleration $\boldsymbol{a}$; however, force and acceleration are not parallel to each other. In fact, for rest-mass-preserving forces one finds $\boldsymbol{F} = \gamma m\boldsymbol{a} + (\boldsymbol{F}\boldsymbol{v})\boldsymbol{v}/c^2$. In contrast, in relativity 3-momentum is *not* proportional to 3-velocity, although it is parallel to it. Challenge 703 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

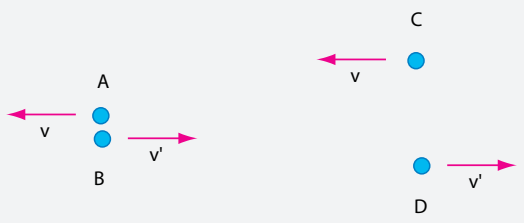

FIGURE 261 On the definition of relative velocity

Challenge 704 e The 4-force, like the 4-acceleration, is orthogonal to the 4-velocity. The meaning of the zeroth component of the 4-force can easily be discerned: it is the *power* required to accelerate the object. One has $\boldsymbol{KU} = c^2 \mathrm{d}m/\mathrm{d}\tau = \gamma^2(\mathrm{d}E/\mathrm{d}t - \boldsymbol{F}\boldsymbol{v})$: this is the proper rate at which the internal energy of a system increases. The product $\boldsymbol{KU}$ vanishes only for rest-mass-conserving forces. Particle collisions that lead to reactions do not belong to this class. In everyday life, the rest mass is preserved, and then one gets the Galilean expression $\boldsymbol{F}\boldsymbol{v} = \mathrm{d}E/\mathrm{d}t$.

Rotation in relativity

If at night we turn around our own axis while looking at the sky, the stars move with a velocity much higher than that of light. Most stars are masses, not images. Their speed should be limited by that of light. How does this fit with special relativity?

This example helps to clarify in another way what the limit velocity actually is. Physically speaking, a rotating sky does *not* allow superluminal energy transport, and thus does not contradict the concept of a limit speed. Mathematically speaking, the speed of light limits relative velocities *only* between objects that come *near* to each other, as shown on the left of Figure 261. To compare velocities of distant objects is only possible if all velocities involved are constant in time; this is not the case in the present example. The differential version of the Lorentz transformations make this point particularly clear. In many general cases, relative velocities of *distant* objects can be higher than the speed Page 436 of light. We encountered one example earlier, when discussing the car in the tunnel, and Page 466 we will encounter a few more examples shortly.

With this clarification, we can now briefly consider *rotation* in relativity. The first question is how lengths and times change in a rotating frame of reference. You may want to check that an observer in a rotating frame agrees with a non-rotating colleague on the radius of a rotating body; however, both find that the rotating body, even if it is Challenge 705 e rigid, has a circumference *different* from the one it had before it started rotating. Sloppily speaking, the value of π *changes* for rotating observers. The ratio between the circumfer- Challenge 706 e ence c and the radius r turns out to be $c/r = 2\pi\gamma$: it increases with rotation speed. This Ref. 359 counter-intuitive result is often called *Ehrenfest's paradox*. Among other things, it shows that space-time for an observer on a rotating disc is *not* the Minkowski space-time of special relativity.

Rotating bodies behave strangely in many ways. For example, one gets into trouble when one tries to synchronize clocks mounted on a rotating circle, as shown in Figure 262 If one starts synchronizing the clock at O_2 with that at O_1, and so on, continuing up to clock O_n, one finds that the last clock is *not* synchronized with the first. This result

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

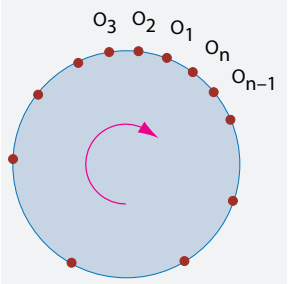

FIGURE 262 Observers on a rotating object

reflects the change in circumference just mentioned. In fact, a careful study shows that the measurements of length and time intervals lead all observers O_k to conclude that they live in a rotating space-time. Rotating discs can thus be used as an introduction to general relativity, where spatial curvature and its effects form the central topic. More about this in the next chapter.

Is angular velocity limited? Yes: the tangential speed in an inertial frame of reference cannot exceed that of light. The limit thus depends on the *size* of the body in question. Challenge 707 s That leads to a neat puzzle: can one *see* an object rotating very rapidly?

We mention that 4-angular momentum is defined naturally as

$$l^{ab} = x^a p^b - x^b p^a \,. \tag{193}$$

In other words, 4-angular momentum is a *tensor*, not a vector, as shown by its two indices. Challenge 708 ny Angular momentum is conserved in special relativity. The moment of inertia is naturally defined as the proportionality factor between angular velocity and angular momentum.

Challenge 709 ny Obviously, for a rotating particle, the rotational energy is part of the rest mass. You may want to calculate the fraction for the Earth and the Sun. It is not large. By the way, Challenge 710 ny how would you determine whether a microscopic particle, too small to be seen, is rotating?

In relativity, rotation and translation combine in strange ways. Imagine a cylinder in uniform rotation along its axis, as seen by an observer at rest. As Max von Laue has discussed, the cylinder will appear *twisted* to an observer moving along the rotation axis. Challenge 711 e Can you confirm this?

Challenge 712 ny Here is a last puzzle about rotation. Velocity is relative; this means that the measured value depends on the observer. Is this the case also for angular velocity?

Wave motion

In Galilean physics, a wave is described by a wave vector and a frequency. In special relativity, the two are combined in the wave 4-vector, given by

$$\boldsymbol{L} = \frac{1}{\lambda}\left(\frac{\omega}{c}, \boldsymbol{n}\right) \,, \tag{194}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where λ is the wavelength, ω the wave velocity, and $\boldsymbol{n}$ the normed direction vector. Suppose an observer with 4-velocity $\boldsymbol{U}$ finds that a wave $\boldsymbol{L}$ has frequency ν. Show that

$$\nu = \boldsymbol{L}\boldsymbol{U} \tag{195}$$

Challenge 713 ny Ref. 311 Challenge 714 ny

must be obeyed. Interestingly, the wave velocity ω transforms in a different way than particle velocity except in the case $\omega = c$. Also the aberration formula for wave motion differs from that for particles, except in the case $\omega = c$.

The action of a free particle – how do things move?

Page 194

If we want to describe relativistic motion of a free particle in terms of an extremal principle, we need a definition of the action. We already know that physical action is a measure of the change occurring in a system. For an inertially moving or free particle, the only change is the ticking of its proper clock. As a result, the action of a free particle will be proportional to the elapsed proper time. In order to get the standard unit of energy times time, or Js, for the action, the first guess for the action of a free particle is

$$S = -mc^2 \int_{\tau_1}^{\tau_2} \mathrm{d}\tau \,, \tag{196}$$

where τ is the proper time along its path. This is indeed the correct expression. It implies conservation of (relativistic) energy and momentum, as the change in proper time is maximal for straight-line motion with constant velocity. Can you confirm this? Indeed, in nature, all particles move in such a way that their proper time is maximal. In other words, we again find that in nature things change as little as possible. Nature is like a wise old man: its motions are as slow as possible. If you prefer, every change is maximally effective. As we mentioned before, Bertrand Russell called this the *law of cosmic laziness*.

Challenge 715 ny

The expression (196) for the action is due to Max Planck. In 1906, by exploring it in detail, he found that the quantum of action $\hbar$, which he had discovered together with the Boltzmann constant, is a relativistic invariant (like the Boltzmann constant k). Can you imagine how he did this?

Challenge 716 ny

The action can also be written in more complex, seemingly more frightening ways. These equivalent ways to write it are particularly appropriate to prepare for general relativity:

$$S = \int L \,\mathrm{d}t = -mc^2 \int_{t_1}^{t_2} \frac{1}{\gamma} \,\mathrm{d}t = -mc \int_{\tau_1}^{\tau_2} \sqrt{u_a u^a} \,\mathrm{d}\tau = -mc \int_{s_1}^{s_2} \sqrt{\eta^{ab} \frac{\mathrm{d}x_a}{\mathrm{d}s} \frac{\mathrm{d}x_b}{\mathrm{d}s}} \,\mathrm{d}s \,, \tag{197}$$

where s is some arbitrary, but monotonically increasing, function of τ, such as τ itself. As usual, the *metric* $\eta^{\alpha\beta}$ of special relativity is

$$\eta^{ab} = \eta_{ab} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 & 0 & 0 \\ 0 & 0 & -1 & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} . \tag{198}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

You can easily confirm the form of the action (197) by deducing the equation of motion in the usual way. Challenge 717 ny

In short, nature is not in a hurry: every object moves in a such way that its own clock shows the *longest* delay possible, compared with any alternative motion nearby.* This general principle is also valid for particles under the influence of gravity, as we will see in the section on general relativity, and for particles under the influence of electric or magnetic interactions. In fact, it is valid in all cases of (macroscopic) motion found in nature. For the moment, we just note that the longest proper time is realized when the difference between kinetic and potential energy is minimal. (Can you confirm this?) For the Galilean case, the longest proper time thus implies the smallest average difference between the two energy types. We thus recover the principle of least action in its Galilean formulation. Challenge 719 ny

Earlier on, we saw that the action measures the change going on in a system. Special relativity shows that nature minimizes change by maximizing proper time. In nature, *proper time is always maximal*. In other words, things move along paths of *maximal ageing*. Can you explain why 'maximal ageing' and 'cosmic laziness' are equivalent? Page 194 Challenge 720 ny

We thus again find that nature is the opposite of a Hollywood film: nature changes in the most economical way possible. The deeper meaning of this result is left to your personal thinking: enjoy it!

Conformal transformations – why is the speed of light constant?

The distinction between space and time in special relativity depends on the observer. On the other hand, all inertial observers agree on the position, shape and orientation of the light cone at a point. Thus, in the theory of relativity, the light cones are the basic physical 'objects'. Given the importance of light cones, we might ask if inertial observers are the only ones that observe the same light cones. Interestingly, it turns out that *other* observers do as well.

The first such category of observers are those using units of measurement in which all time and length intervals are multiplied by a *scale factor* λ. The transformations among these points of view are given by

$$x_a \mapsto \lambda x_a \tag{199}$$

and are called *dilations*.

A second category of additional observers are found by applying the so-called *special conformal transformations*. These are compositions of an *inversion*

$$x_a \mapsto \frac{x_a}{x^2} \tag{200}$$

with a *translation* by a vector b_a, namely

$$x_a \mapsto x_a + b_a \,, \tag{201}$$

* If neutrinos were massless, the action (197) would not be applicable for them. Why? Can you find an alternative for this (admittedly academic) case? Challenge 718 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

and a second inversion. Thus the special conformal transformations are

$$x_a \mapsto \frac{x_a + b_a x^2}{1 + 2b_a x^a + b^2 x^2} \quad \text{or} \quad \frac{x_a}{x^2} \mapsto \frac{x_a}{x^2} + b_a \,. \tag{202}$$

These transformations are called *conformal* because they do not change angles of (in-
Challenge 721 ny finitesimally) small shapes, as you may want to check. They therefore leave the *form* (of infinitesimally small objects) unchanged. For example, they transform infinitesimal circles into infinitesimal circles. They are called *special* because the *full* conformal group includes the dilations and the inhomogeneous Lorentz transformations as well.*

Note that the way in which special conformal transformations leave light cones invari-
Challenge 723 ny ant is rather subtle.

Since dilations do not commute with time translations, there is no conserved quantity associated with this symmetry. (The same is true of Lorentz boosts.) In contrast, rotations and spatial translations do commute with time translations and thus do lead to conserved quantities.

In summary, vacuum is conformally invariant – in the special sense just mentioned – and thus also dilation invariant. This is another way to say that vacuum alone is not sufficient to define lengths, as it does not fix a scale factor. As we would expect, matter is necessary to do so. Indeed, (special) conformal transformations are not symmetries of situations containing matter. Only vacuum is conformally invariant; nature as a whole is not.

However, conformal invariance, or the invariance of light cones, is sufficient to allow velocity measurements. Conformal invariance is also *necessary* for velocity measure-
Challenge 724 ny ments, as you might want to check.

We have seen that conformal invariance implies inversion symmetry: that is, that the large and small scales of a vacuum are related. This suggest that the constancy of the speed of light is related to the existence of inversion symmetry. This mysterious connection gives us a glimpse of the adventures we will encounter in the final part of our ascent of Motion Mountain. Conformal invariance turns out to be an important property that will lead to some incredible insights.**

Challenge 722 ny * The set of all *special* conformal transformations forms a group with four parameters; adding dilations and the inhomogeneous Lorentz transformations one gets fifteen parameters for the *full* conformal group. The conformal group is locally isomorphic to SU(2,2) and to the simple group SO(4,2): these concepts are
Page 875 explained in Appendix B. Note that all this is true only for *four* space-time dimensions; in *two* dimensions – the other important case, especially in string theory – the conformal group is isomorphic to the group of arbitrary analytic coordinate transformations, and is thus infinite-dimensional.

** The conformal group does not appear only in the kinematics of special relativity: it is the symmetry group of all physical interactions, such as electromagnetism, provided that all the particles involved have zero mass, as is the case for the photon. A field that has mass cannot be conformally invariant; therefore conformal invariance is not an exact symmetry of all of nature. Can you confirm that a mass term $m\varphi^2$ in
Challenge 725 ny a Lagrangian is not conformally invariant?

However, since all particles observed up to now have masses that are many orders of magnitude smaller than the Planck mass, it can be said that they have almost vanishing mass; conformal symmetry can then be seen as an *approximate* symmetry of nature. In this view, all massive particles should be seen as small corrections, or perturbations, of massless, i.e., conformally invariant, fields. Therefore, for the construction of a fundamental theory, conformally invariant Lagrangians are often assumed to provide a good starting

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

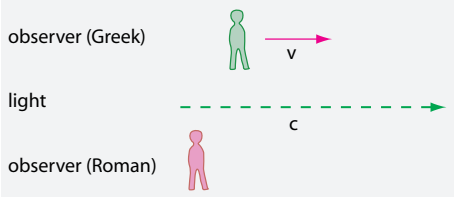

FIGURE 263 The simplest situation for an inertial and an accelerated observer

ACCELERATING OBSERVERS

So far, we have only studied what inertial, or free-flying, observers say to each other when they talk about the same observation. For example, we saw that moving clocks always run slow. The story gets even more interesting when one or both of the observers are accelerating.

One sometimes hears that special relativity cannot be used to describe accelerating observers. That is wrong, just as it is wrong to say that Galilean physics cannot be used for accelerating observers. Special relativity's only limitation is that it cannot be used in non-flat, i.e., curved, space-time. Accelerating bodies do exist in flat space-times, and therefore they can be discussed in special relativity.

Ref. 360 As an appetizer, let us see what an accelerating, Greek, observer says about the clock of an inertial, Roman, one, and vice versa. Assume that the Greek observer, shown in Figure 263, moves along the path $\boldsymbol{x}(t)$, as observed by the inertial Roman one. In general, the Roman/Greek clock rate ratio is given by $\Delta\tau/\Delta t = (\tau_2 - \tau_1)/(t_2 - t_1)$. Here the Greek coordinates are constructed with a simple procedure: take the two sets of events defined by $t = t_1$ and $t = t_2$, and let τ_1 and τ_2 be the points where these sets intersect the time axis of the Greek observer.* We assume that the Greek observer is inertial and moving with velocity v as observed by the Roman one. The clock ratio of a Greek observer is then given by

$$\frac{\Delta\tau}{\Delta t} = \frac{\mathrm{d}\tau}{\mathrm{d}t} = \sqrt{1 - v^2/c^2} = \frac{1}{\gamma_v} \,, \tag{203}$$

Challenge 726 ny a formula we are now used to. We find again that moving clocks run slow.

Ref. 360 For accelerated motions, the differential version of the above reasoning is necessary. The Roman/Greek clock rate ratio is again $\mathrm{d}\tau/\mathrm{d}t$, and τ and $\tau + \mathrm{d}\tau$ are calculated in the same way from the times t and $t + \mathrm{d}t$. Assume again that the Greek observer moves along the path $\boldsymbol{x}(t)$, as measured by the Roman one. We find directly that

$$\tau = t - \boldsymbol{x}(t)\boldsymbol{v}(t)/c^2 \tag{204}$$

and thus

$$\tau + \mathrm{d}\tau = (t + \mathrm{d}t) - [\boldsymbol{x}(t) - \mathrm{d}t\boldsymbol{v}(t)][\boldsymbol{v}(t) + \mathrm{d}t\boldsymbol{a}(t)]/c^2 \,. \tag{205}$$

approximation.

* These sets form what mathematicians call *hypersurfaces*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Together, these equations yield

$$\text{`}\mathrm{d}\tau/\mathrm{d}t\text{'} = \gamma_v(1 - \boldsymbol{v}\boldsymbol{v}/c^2 - \boldsymbol{x}\boldsymbol{a}/c^2) \ . \tag{206}$$

This shows that accelerated clocks can run *fast* or slow, depending on their position $\boldsymbol{x}$ and the sign of their acceleration $\boldsymbol{a}$. There are quotes in the above equation because we can see directly that the Greek observer notes

$$\text{`}\mathrm{d}t/\mathrm{d}\tau\text{'} = \gamma_v \ , \tag{207}$$

which is *not* the inverse of equation (206). This difference becomes most apparent in the simple case of two clocks with the same velocity, one of which has a constant acceleration g towards the origin, whereas the other moves inertially. We then have

$$\text{`}\mathrm{d}\tau/\mathrm{d}t\text{'} = 1 + gx/c^2 \tag{208}$$

and

$$\text{`}\mathrm{d}t/\mathrm{d}\tau\text{'} = 1 \ . \tag{209}$$

We will discuss this situation shortly. But first we must clarify the concept of acceleration.

Acceleration for inertial observers

Accelerations behave differently from velocities under change of viewpoint. Let us first take the simple case in which the object and two inertial observers all move along the x-axis. If the Roman inertial observer measures an acceleration $a = \mathrm{d}v/\mathrm{d}t = \mathrm{d}^2x/\mathrm{d}t^2$, and the Greek observer, also inertial, measures an acceleration $\alpha = \mathrm{d}\omega/\mathrm{d}\tau = \mathrm{d}^2\xi/\mathrm{d}\tau^2$, we get

Ref. 312

$$\gamma_v^3 a = \gamma_\omega^3 \alpha \ . \tag{210}$$

This relation shows that accelerations are *not* Lorentz invariant, unless the velocities are small compared to the speed of light. This is in contrast to our everyday experience, where accelerations are independent of the speed of the observer.

Expression (210) simplifies if the accelerations are measured at a time t at which ω vanishes – i.e., if they are measured by the so-called *comoving* inertial observer. In that case the acceleration relation is given by

$$a_\mathrm{c} = a\gamma_v^3 \tag{211}$$

and the acceleration $a_\mathrm{c} = \alpha$ is also called proper acceleration, as its value describes what the Greek, comoving observer *feels*: proper acceleration describes the experience of being pushed into the back of the accelerating seat.

In general, the observer's speed and the acceleration are not parallel. We can calculate how the value of 3-acceleration $\boldsymbol{a}$ measured by a general inertial observer is related to the value $\boldsymbol{a}_\mathrm{c}$ measured by the comoving observer using expressions (184) and (182). We

Ref. 361

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

get the generalization of (211):

$$\boldsymbol{v}\boldsymbol{a}_c = \boldsymbol{v}\boldsymbol{a}\gamma_v^3 \tag{212}$$

and

$$\boldsymbol{a} = \frac{1}{\gamma_v^2}\left(\boldsymbol{a}_c - \frac{(1-\gamma_v)(\boldsymbol{v}\boldsymbol{a}_c)\boldsymbol{v}}{v^2} - \frac{\gamma_v(\boldsymbol{v}\boldsymbol{a}_c)\boldsymbol{v}}{c^2}\right) . \tag{213}$$

Squaring yields the relation

$$a^2 = \frac{1}{\gamma_v^4}\left(a_c^2 - \frac{(\boldsymbol{a}_c\boldsymbol{v})^2}{c^2}\right) \tag{214}$$

Page 450

which we know already in a slightly different form. It shows (again) that the comoving or proper 3-acceleration is always larger than the 3-acceleration measured by an outside inertial observer. The faster the outside inertial observer is moving, the smaller the acceleration he observes. Acceleration is not a relativistic invariant. The expression also shows that whenever the speed is perpendicular to the acceleration, a boost yields a factor γ_v^2, whereas a speed parallel to the acceleration gives the already mentioned γ_v^3 dependence.

Challenge 727 e

We see that acceleration complicates many issues, and it requires a deeper investigation. To keep matters simple, from now on we only study *constant* accelerations. Interestingly, this situation serves also as a good introduction to black holes and, as we will see shortly, to the universe as a whole.

Page 604

Accelerating frames of reference

How do we check whether we live in an inertial frame of reference? Let us first define the term. An *inertial frame* (*of reference*) has two defining properties. First, lengths and distances measured with a ruler are described by Euclidean geometry. In other words, rulers behave as they do in daily life. In particular, distances found by counting how many rulers (rods) have to be laid down end to end to reach from one point to another – the so-called *rod distances* – behave as in everyday life. For example, they obey Pythagoras' theorem in the case of right-angled triangles. Secondly, the speed of light is constant. In other words, any two observers in that frame, independent of their time and of the position, make the following observation: the ratio c between twice the rod distance between two points and the time taken by light to travel from one point to the other and back is always the same.

Equivalently, an inertial frame is one for which all clocks always remain synchronized and whose geometry is Euclidean. In particular, in an inertial frame all observers at fixed coordinates always remain at rest with respect to each other. This last condition is, however, a more general one. There are other, non-inertial, situations where this is still the case.

Non-inertial frames, or *accelerating frames*, are a useful concept in special relativity. In fact, we all live in such a frame. We can use special relativity to describe it in the same way that we used Galilean physics to describe it at the beginning of our journey.

A general *frame of reference* is a continuous set of observers remaining at rest with respect to each other. Here, 'at rest with respect to each other' means that the time for a

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

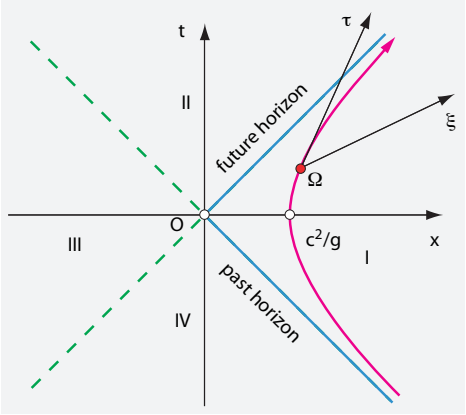

FIGURE 264 The hyperbolic motion of an rectilinearly, uniformly accelerating observer Ω

light signal to go from one observer to another and back again is constant over time, or equivalently, that the rod distance between the two observers is constant. Any frame of reference can therefore also be called a *rigid* collection of observers. We therefore note that a general frame of reference is *not* the same as a set of coordinates; the latter is usually *not* rigid. If all the rigidly connected observers have constant coordinate values, we speak of a *rigid coordinate system*. Obviously, these are the most useful when it comes to describing accelerating frames of reference.*

Ref. 363 Note that if two observers both move with a velocity $\boldsymbol{v}$, as measured in some *inertial* frame, they observe that they are at rest with respect to each other *only* if this velocity is *constant*. Again we find, as above, that two people tied to each other by a rope, and at a distance such that the rope is under tension, will see the rope break (or hang loose) if they accelerate together to (or decelerate from) relativistic speeds in precisely the same way. Relativistic acceleration requires careful thinking.

Challenge 728 ny

An observer who always *feels* the *same* force on his body is called *uniformly* accelerating. More precisely, a uniformly accelerating observer is an observer whose acceleration at every moment, measured by the inertial frame with respect to which the observer is at rest *at that moment*, always has the same value $\boldsymbol{B}$. It is important to note that uniform acceleration is *not* uniformly accelerating when always observed from the *same* inertial frame. This is an important difference from the Galilean case.

For uniformly accelerated motion in the sense just defined, we need

$$\boldsymbol{B} \cdot \boldsymbol{B} = -g^2 \tag{215}$$

Ref. 364 where g is a constant independent of t. The simplest case is uniformly accelerating mo-

Ref. 362 * There are essentially only two other types of rigid coordinate frames, apart from the inertial frames:

— The frame $ds^2 = dx^2 + dy^2 + dz^2 - c^2 dt^2 (1 + g_k x_k/c^2)^2$ with arbitrary, but constant, acceleration of the origin. The acceleration is $\boldsymbol{a} = -\boldsymbol{g}(1 + \boldsymbol{g}x/c^2)$.
— The uniformly rotating frame $ds^2 = dx^2 + dy^2 + dz^2 + 2\omega(-y\,dx + x\,dy)dt - (1 - r^2\omega^2/c^2)dt$. Here the z-axis is the rotation axis, and $r^2 = x^2 + y^2$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tion that is also *rectilinear*, i.e., for which the acceleration $\boldsymbol{a}$ is parallel to $\boldsymbol{v}$ at one instant of time and (therefore) for all other times as well. In this case we can write, using 3-vectors,

Challenge 729 ny

$$\gamma^3 \boldsymbol{a} = \boldsymbol{g} \quad \text{or} \quad \frac{\mathrm{d}\gamma \boldsymbol{v}}{\mathrm{d}t} = \boldsymbol{g} \,. \tag{216}$$

Taking the direction we are talking about to be the x-axis, and solving for $v(t)$, we get

$$v = \frac{gt}{\sqrt{1 + \frac{g^2 t^2}{c^2}}} \,, \tag{217}$$

where it was assumed that $v(0) = 0$. We note that for small times we get $v = gt$ and for large times $v = c$, both as expected. The momentum of the accelerated observer increases linearly with time, again as expected. Integrating, we find that the accelerated observer moves along the path

Challenge 730 ny

$$x(t) = \frac{c^2}{g} \sqrt{1 + \frac{g^2 t^2}{c^2}} \,, \tag{218}$$

where it is assumed that $x(0) = c^2/g$, in order to keep the expression simple. Because of this result, visualized in Figure 264, a rectilinearly and uniformly accelerating observer is said to undergo *hyperbolic* motion. For small times, the world-line reduces to the usual $x = gt^2/2 + x_0$, whereas for large times it is $x = ct$, as expected. The motion is thus uniformly accelerated only for the moving body itself, *not* for an outside observer.

The proper time τ of the accelerated observer is related to the time t of the inertial frame in the usual way by $\mathrm{d}t = \gamma \mathrm{d}\tau$. Using the expression for the velocity $v(t)$ of equation (217) we get*

Ref. 364, Ref. 365

$$t = \frac{c}{g} \sinh \frac{g\tau}{c} \quad \text{and} \quad x = \frac{c^2}{g} \cosh \frac{g\tau}{c} \tag{219}$$

for the relationship between proper time τ and the time t and position x measured by the external, inertial Roman observer. We will encounter this relation again during our study of black holes.

Does all this sound boring? Just imagine accelerating on a motorbike at $g = 10\,\mathrm{m/s^2}$ for the proper time τ of 25 years. That would bring you beyond the end of the known universe! Isn't that worth a try? Unfortunately, neither motorbikes nor missiles that accelerate like this exist, as their fuel tanks would have to be enormous. Can you confirm this?

Challenge 731 s

Ref. 366

* Use your favourite mathematical formula collection – every student should have one – to deduce this. The *hyperbolic sine* and the *hyperbolic cosine* are defined by $\sinh y = (\mathrm{e}^y - \mathrm{e}^{-y})/2$ and $\cosh y = (\mathrm{e}^y + \mathrm{e}^{-y})/2$. They imply that $\int \mathrm{d}y/\sqrt{y^2 + a^2} = \operatorname{arsinh} y/a = \operatorname{Arsh} y/a = \ln(y + \sqrt{y^2 + a^2})$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

For uniform acceleration, the coordinates transform as

$$\begin{aligned} t &= \left(\frac{c}{g} + \frac{\xi}{c}\right) \sinh \frac{g\tau}{c} \\ x &= \left(\frac{c^2}{g} + \xi\right) \cosh \frac{g\tau}{c} \\ y &= \upsilon \\ z &= \zeta \,, \end{aligned} \tag{220}$$

where τ now is the time coordinate in the Greek frame. We note also that the space-time interval $\mathrm{d}\sigma$ satisfies

$$\mathrm{d}\sigma^2 = (1 + g\xi/c^2)^2 c^2 \mathrm{d}\tau^2 - \mathrm{d}\xi^2 - \mathrm{d}\upsilon^2 - \mathrm{d}\zeta^2 = c^2 \mathrm{d}t^2 - \mathrm{d}x^2 - \mathrm{d}y^2 - \mathrm{d}z^2 \,, \tag{221}$$

and since for $\mathrm{d}\tau = 0$ distances are given by Pythagoras' theorem, the Greek reference frame is indeed rigid.

Ref. 367

After this forest of formulae, let's tackle a simple question, shown in Figure 264. The inertial, Roman observer O sees the Greek observer Ω departing with acceleration g, moving further and further away, following equation (218). What does the Greek observer say about his Roman colleague? With all the knowledge we have now, that is easy to answer. At each point of his trajectory Ω sees that O has the coordinate $\tau = 0$ (can you confirm this?), which means that the distance to the Roman observer, as seen by the Greek one, is the same as the space-time interval OΩ. Using expression (218), we see that this is

Challenge 732 e

Ref. 368

$$d_{\mathrm{O}\Omega} = \sqrt{\xi^2} = \sqrt{x^2 - c^2 t^2} = c^2/g \,, \tag{222}$$

which, surprisingly enough, is constant in time! In other words, the Greek observer will observe that he stays at a constant distance from the Roman one, in complete contrast to what the Roman observer says. Take your time to check this strange result in some other way. We will need it again later on, to explain why the Earth does not explode. (Can you guess how that is related to this result?)

Challenge 733 s

The composition theorem for accelerations is more complex than for velocities. A good explanation of this was published by Mishra. If we call a_{nm} the acceleration of system n by observer m, we are seeking to express the object acceleration a_{01} as function of the value a_{02} measured by the other observer, the relative acceleration a_{12}, and the proper acceleration a_{22} of the other observer: see Figure 265. Here we will only study one-dimensional situations, where all observers and all objects move along one axis. (For clarity, we also write $v_{11} = v$ and $v_{02} = u$.) In Galilean physics we have the general connection

Ref. 369

Challenge 734 e

$$a_{01} = a_{02} - a_{12} + a_{22} \tag{223}$$

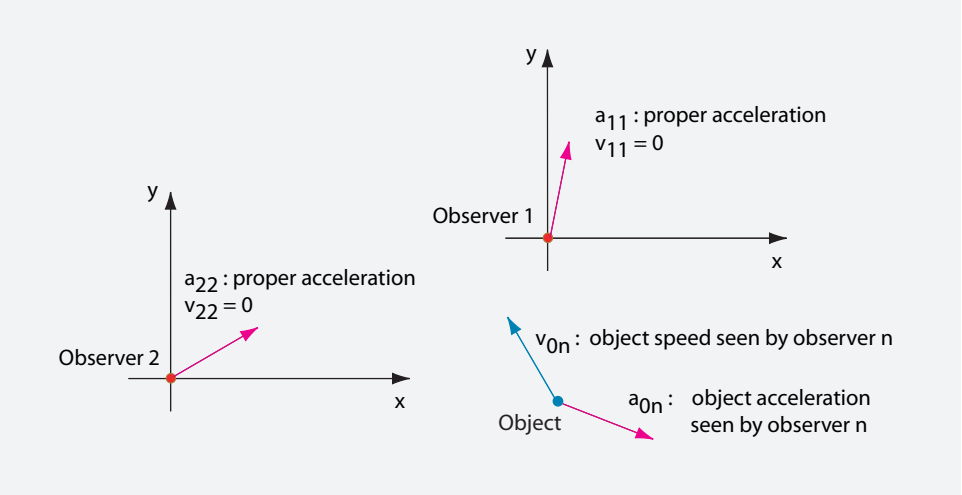

FIGURE 265 The definitions necessary to deduce the composition behaviour of accelerations

because accelerations behave simply. In special relativity, one gets

$$a_{01} = a_{02}\frac{(1-v^2/c^2)^{3/2}}{(1-uv/c^2)^3} - a_{12}\frac{(1-u^2/c^2)(1-v^2/c^2)^{-1/2}}{(1-uv/c^2)^2} + a_{22}\frac{(1-u^2/c^2)(1-v^2/c^2)^{3/2}}{(1-uv/c^2)^3} \tag{224}$$

Challenge 735 ny and you might enjoy checking the expression.

Page 440 Challenge 736 ny Can you state how the acceleration ratio enters into the definition of mass in special relativity?

Event horizons

There are many surprising properties of accelerated motion. Of special interest is the trajectory, in the coordinates ξ and τ of the rigidly accelerated frame, of an object located at the departure point $x = x_0 = c^2/g$ at all times t. One gets the two relations*

Challenge 737 ny

$$\xi = -\frac{c^2}{g}\left(1 - \operatorname{sech}\frac{g\tau}{c}\right)$$
$$\mathrm{d}\xi/\mathrm{d}\tau = -c\,\operatorname{sech}\frac{g\tau}{c}\tanh\frac{g\tau}{c}\,. \tag{226}$$

These equations are strange. For large times τ the coordinate ξ approaches the limit value $-c^2/g$ and $\mathrm{d}\xi/\mathrm{d}\tau$ approaches zero. The situation is similar to that of a car accelerating

* The functions appearing above, the *hyperbolic secant* and the *hyperbolic tangent*, are defined using the expressions from the footnote on page 462:

$$\operatorname{sech}\ y = \frac{1}{\cosh\ y} \quad \text{and} \quad \tanh\ y = \frac{\sinh\ y}{\cosh\ y}\,. \tag{225}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

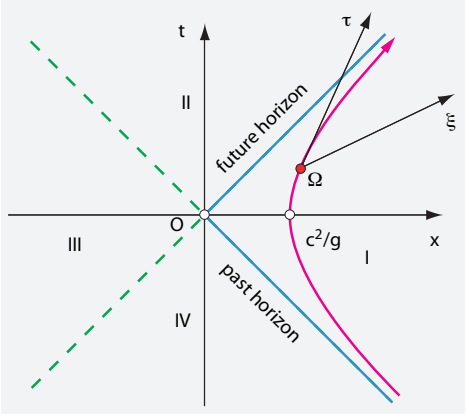

FIGURE 266 Hyperbolic motion and event horizons

away from a woman standing on a long road. Seen from the car, the woman moves away; however, after a while, the only thing one notices is that she is slowly approaching the horizon. In Galilean physics, both the car driver and the woman on the road see the other person approaching their horizon; in special relativity, only the accelerated observer makes this observation.

A graph of the situation helps to clarify the result. In Figure 266 we can see that light emitted from any event in regions II and III cannot reach the Greek observer. Those events are hidden from him and cannot be observed. Strangely enough, however, light from the Greek observer *can* reach region II. The boundary between the part of space-time that can be observed and the part that cannot is called the *event horizon*. In relativity, event horizons act like one-way gates for light and other signals. For completeness, the graph also shows the past event horizon. Can you confirm that event horizons are *black*?

Challenge 738 ny

So, not all events observed in an inertial frame of reference can be observed in a uniformly accelerating frame of reference. Uniformly accelerating frames of reference produce event horizons at a distance $-c^2/g$. For example, a person who is standing can never see further than this distance below his feet.

By the way, is it true that a light beam cannot catch up with an observer in hyperbolic motion, if the observer has a sufficient head start?

Challenge 739 s

Here is a more advanced challenge, which prepares us for general relativity. What is the *shape* of the horizon seen by a uniformly accelerated observer?

Challenge 740 s

Acceleration changes colours

We saw earlier that a moving receiver sees different colours from the sender. So far, we discussed this colour shift, or Doppler effect, for inertial motion only. For accelerating frames the situation is even stranger: sender and receiver do not agree on colours even if they are at *rest* with respect to each other. Indeed, if light is emitted in the direction of the acceleration, the formula for the space-time interval gives

Ref. 364, Ref. 370

$$d\sigma^2 = \left(1 + \frac{g_0 x}{c^2}\right)^2 c^2 dt^2 \qquad (227)$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

in which g_0 is the proper acceleration of an observer located at $x = 0$. We can deduce in a straightforward way that Challenge 741 ny

$$\frac{f_r}{f_s} = 1 - \frac{g_r h}{c^2} = \frac{1}{1 + \frac{g_s h}{c^2}} \tag{228}$$

where h is the rod distance between the source and the receiver, and where $g_s = g_0/(1 + g_0 x_s/c^2)$ and $g_r = g_0/(1 + g_o x_r/c^2)$ are the proper accelerations measured at the source and at the detector. In short, the frequency of light decreases when light moves in the direction of acceleration. By the way, does this have an effect on the colour of trees along their vertical extension? Challenge 742 s

The formula usually given, namely

$$\frac{f_r}{f_s} = 1 - \frac{gh}{c^2}\,, \tag{229}$$

is only correct to a first approximation. In accelerated frames of reference, we have to be careful about the meaning of every quantity. For everyday accelerations, however, the differences between the two formulae are negligible. Can you confirm this? Challenge 743 ny

Can light move faster than c?

What speed of light does an accelerating observer measure? Using expression (229) above, an accelerated observer deduces that

$$v_{\text{light}} = c\left(1 + \frac{gh}{c^2}\right) \tag{230}$$

which is higher than c for light moving in front of or 'above' him, and lower than c for light moving behind or 'below' him. This strange result follows from a basic property of any accelerating frame of reference. In such a frame, even though all observers are at rest with respect to each other, clocks do *not* remain synchronized. This change of the speed of light has also been confirmed by experiment.* Thus, the speed of light is only constant when it is defined as $c = \mathrm{d}x/\mathrm{d}t$, *and* if $\mathrm{d}x$ and $\mathrm{d}t$ are measured with a ruler located at a point *inside* the interval $\mathrm{d}x$ and a clock read off *during* the interval $\mathrm{d}t$. If the speed of light is defined as $\Delta x/\Delta t$, or if the ruler defining distances or the clock measuring times is located away from the propagating light, the speed of light is different from c for accelerating observers! This is the same effect you can experience when you turn around your vertical axis at night: the star velocities you observe are much higher than the speed of light.

Note that this result does not imply that signals or energy can be moved faster than c. You may want to check this for yourself. Challenge 744 s

In fact, all these effects are negligible for distances l that are much less than c^2/a. For an acceleration of $9.5\,\mathrm{m/s^2}$ (about that of free fall), distances would have to be of the order of one light year, or $9.5 \cdot 10^{12}$ km, in order for any sizable effects to be observed. In short, *c is the speed of light relative to* nearby *matter only.*

* The propagation delays to be discussed in general relativity can be seen as confirmations of this effect. Page 535

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

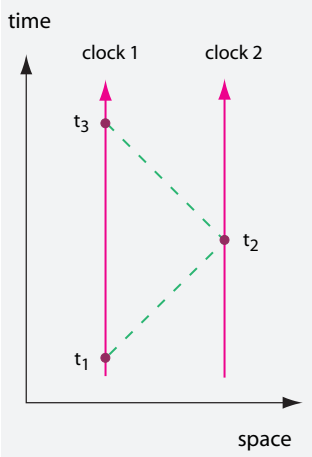

FIGURE 267 Clocks and the measurement of the speed of light as two-way velocity

By the way, everyday gravity is equivalent to a constant acceleration. So, why then do distant objects, such as stars, not move faster than light, following expression (230)?

Challenge 745 s

What is the speed of light?

We have seen that the speed of light, as usually defined, is given by c only if either the observer is inertial or the observer measures the speed of light passing nearby (rather than light passing at a distance). In short, the speed of light has to be measured locally. But this condition does not eliminate all subtleties.

An additional point is often forgotten. Usually, length is measured by the time it takes light to travel. In such a case the speed of light will obviously be constant. But how does one check the constancy? One needs to eliminate length measurements. The simplest way to do this is to reflect light from a mirror, as shown in Figure 267. The constancy of the speed of light implies that if light goes up and down a short straight line, then the clocks at the two ends measure times given by

$$t_3 - t_1 = 2\,(t_2 - t_1)\ . \tag{231}$$

Here it is assumed that the clocks have been synchronised according to the prescription on page 428. If the factor were not exactly two, the speed of light would not be constant. In fact, all experiments so far have yielded a factor of two, within measurement errors.*

* The subtleties of the one-way and two-way speed of light have been a point of discussion for a long time. It has been often argued that a factor different than two, which would lead to a distinction between the one-way speed of light and the two-way speed of light, cannot be ruled out by experiment, as long as the two-way speed of light remains c for all observers.

Many experiments on the one-way velocity of light are explained and discussed in Ref. 317. Zhang says in his summary on page 171, that the one-way velocity of light is indeed independent of the light source; however, no experiment really shows that it is equal to the two-way velocity. Moreover, almost all so-called 'one-way' experiments are in fact still hidden 'two-way' experiments (see his page 150).

Ref. 371

Ref. 372 In 2004, Hans Ohanian showed that the question can be settled by discussing how a non-standard one-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

This result is sometimes expressed by saying that it is impossible to measure the *one-way velocity of light*; only the *two-way* velocity of light is measurable. Do you agree? Challenge 746 s

Limits on the length of solid bodies

An everyday solid object breaks when some part of it moves with respect to some other part with more than the speed of sound c of the material.* For example, when an object hits the floor and its front end is stopped within a distance d, the object breaks at the latest when

$$\frac{v^2}{c^2} \geqslant \frac{2d}{l} \,. \tag{232}$$

In this way, we see that we can avoid the breaking of fragile objects by packing them into foam rubber – which increases the stopping distance – of roughly the same thickness as the object's size. This may explain why boxes containing presents are usually so much larger than their contents!

The fracture limit can also be written in a different way. To avoid breaking, the acceleration a of a solid body with length l must obey

$$la < c^2 \,, \tag{233}$$

where c is the speed of sound, which is the speed limit for the material parts of solids. Let us now repeat the argument in relativity, using the speed of light instead of that of sound. Imagine accelerating the front of a *solid* body with some *proper* acceleration a. The back end cannot move with an acceleration α equal or larger than infinity, or if one prefers, it cannot move with more than the speed of light. A quick check shows that therefore the length l of a solid body must obey Ref. 373 Challenge 747 s

$$l\alpha < c^2/2 \,, \tag{234}$$

where c is now the speed of light. The speed of light thus limits the size of solid bodies. For example, for 9.8 m/s^2, the acceleration of good motorbike, this expression gives a length limit of 9.2 Pm, about a light year. Not a big restriction: most motorbikes are shorter.

However, there are other, more interesting situations. The highest accelerations achievable today are produced in particle accelerators. Atomic nuclei have a size of a few femtometres. Can you deduce at which energies they break when smashed together in an accelerator? In fact, inside a nucleus, the nucleons move with accelerations of the order of $v^2/r \approx \hbar^2/m^2r^3 \approx 10^{31}\,\mathrm{m/s^2}$; this is one of the highest values found in nature. Challenge 748 ny

Note that Galilean physics and relativity produce a similar conclusion: a limiting speed, be it that of sound or that of light, makes it impossible for solid bodies to be *rigid*. When we push one end of a body, the other end always moves a little bit later.

way speed of light would affect dynamics. He showed that a non-standard one-way speed of light would introduce pseudoaccelerations and pseudoforces (similar to the Coriolis acceleration and force); since these pseudoaccelerations and pseudoforces are not observed, the one-way speed of light is the same as the two-way speed of light.

* The (longitudinal) speed of sound is about 5.9 km/s for glass, iron or steel; about 4.5 km/s for gold; and about 2 km/s for lead. Other sound speeds are given on page 230.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

A puzzle: does the speed limit imply a relativistic 'indeterminacy relation'

$$\Delta l \, \Delta a \leqslant c^2 \tag{235}$$

Page 1459 for the length and acceleration indeterminacies?

What does all this mean for the size of elementary particles? Take two electrons a distance d apart, and call their size l. The acceleration due to electrostatic repulsion then
Challenge 749 ny leads to an upper limit for their size given by

$$l < \frac{4\pi\varepsilon_0 c^2 d^2 m}{e^2} \,. \tag{236}$$

The nearer electrons can get, the smaller they must be. The present experimental limit gives a size smaller than 10^{-19} m. Can electrons be exactly point-like? We will come back to this question during our study of general relativity and quantum theory.

SPECIAL RELATIVITY IN FOUR SENTENCES

This section of our ascent of Motion Mountain can be quickly summarized.

— All (free floating) observers find that there is a unique, perfect velocity in nature, namely a common maximum energy velocity, which is realized by massless radiation such as light or radio signals, but cannot be achieved by material systems.
— Therefore, even though space-time is the same for every observer, times and lengths vary from one observer to another, as described by the Lorentz transformations (146) and (147), and as confirmed by experiment.
— Collisions show that a maximum speed implies that mass is concentrated energy, and that the total energy of a body is given by $E = \gamma mc^2$, as again confirmed by experiment.
— Applied to accelerated objects, these results lead to numerous counter-intuitive consequences, such as the twin paradox, the appearance of event horizons and the appearance of short-lived tachyons in collisions.

Special relativity shows that motion, though limited in speed, is relative, defined using the propagation of light, conserved, reversible and deterministic.

Could the speed of light vary?

The speed of massless light is the limit speed. Assuming that all light is indeed massless, could the speed of light still change from place to place, or as time goes by? This tricky question still makes a fool out of many physicists. The first answer is usually a loud: 'Yes, of course! Just look at what happens when the value of c is changed in formulae.' (In fact, there have even been attempts to build 'variable speed of light theories'.) However, this
Ref. 374 often-heard answer is wrong.

Since the speed of light enters into our definition of time and space, it thus enters, even if we do not notice it, into the construction of all rulers, all measurement standards

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

and all measuring instruments. Therefore there is no way to detect whether the value actually varies. No imaginable experiment could detect a variation of the limit speed, as the limit speed is the basis for all measurements. 'That is intellectual cruelty!', you might say. 'All experiments show that the speed of light is invariant; we had to swallow one counter-intuitive result after another to accept the constancy of the speed of light, and now we are supposed to admit that there is no other choice?' Yes, we are. That is the irony of progress in physics. The observer-invariance of the speed of light is counter-intuitive and astonishing when compared to the lack of observer-invariance at everyday, Galilean speeds. But had we taken into account that every speed measurement is – whether we like it or not – a comparison with the speed of light, we would not have been astonished by the constancy of the speed of light; rather, we would have been astonished by the strange properties of *small* speeds.

Challenge 750 s

In short, there is in principle *no* way to check the invariance of a standard. To put it another way, the truly surprising aspect of relativity is not the invariance of c; it is the disappearance of c from the formulae of everyday motion.

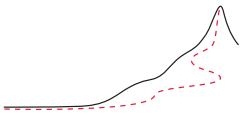
What happens near the speed of light?

As one approaches the speed of light, the quantities in the Lorentz transformation diverge. A division by zero is impossible: indeed, neither masses nor observers can move at the speed of light. However, this is only half the story.

No observable actually diverges in nature. Approaching the speed of light as nearly as possible, even special relativity breaks down. At extremely large Lorentz contractions, there is no way to ignore the curvature of space-time; indeed, gravitation has to be taken into account in those cases. Near horizons, there is no way to ignore the fluctuations of speed and position; quantum theory has to be taken into account there. The exploration of these two limitations define the next two stages of our ascent of Motion Mountain.

At the start of our adventure, during our exploration of Galilean physics, once we had defined the basic concepts of velocity, space and time, we turned our attention to gravitation. The invariance of the speed of light has forced us to change these basic concepts. We now return to the study of gravitation in the light of this invariance.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 16

GENERAL RELATIVITY: GRAVITATION, MAXIMUM SPEED AND MAXIMUM FORCE

General relativity is easy. Nowadays, it can be made as intuitive as universal gravity and its inverse square law – by using the right approach. The main ideas of general relativity, like those of special relativity, are accessible to secondary-school students. Black holes, gravitational waves, space-time curvature and the limits of the universe can then be understood as easily as the Doppler effect or the twins paradox.

We will discover that, just as special relativity is based on a maximum speed c, general relativity is based on a maximum force $c^4/4G$ or on a maximum power $c^5/4G$. We first show that all known experimental data are consistent with these limits. In fact, we find that the maximum force and the maximum power are achieved only on insurmountable limit surfaces; these limit surfaces are called *horizons*. We will then be able to deduce the field equations of general relativity. In particular, the existence of a maximum for force or power implies that space-time is curved. It explains why the sky is dark at night, and it shows that the universe is of finite size.

We also discuss the main counter-arguments and paradoxes arising from the limits. The resolutions of the paradoxes clarify why the limits have remained dormant for so long, both in experiments and in teaching.

After this introduction, we will study the effects of relativistic gravity in more detail. In particular, we will study the consequences of space-time curvature for the motions of bodies and of light in our everyday environment. For example, the inverse square law will be modified. (Can you explain why this is necessary in view of what we have learned so far?) Most fascinating of all, we will discover how to move and bend the vacuum. Then we will study the universe at large; finally, we will explore the most extreme form of gravity: black holes.

Challenge 751 s

Maximum force – general relativity in one statement

> One of the principal objects of theoretical research in any department of knowledge is to find the point of view from which the subject appears in its greatest simplicity.
>
> Willard Gibbs

Ref. 375

We just saw that the theory of *special* relativity appears when we recognize the speed limit c in nature and take this limit as a basic principle. At the turn of the twenty-first century it was shown that *general* relativity can be approached by using a similar basic principle:

Ref. 376, Ref. 378

▷ *There is in nature a maximum force:*

$$F \leqslant \frac{c^4}{4G} = 3.0 \cdot 10^{43}\,\mathrm{N}\,. \tag{237}$$

In nature, no force in any muscle, machine or system can exceed this value. For the curious, the value of the force limit is the energy of a (Schwarzschild) black hole divided by twice its radius. The force limit can be understood intuitively by noting that (Schwarzschild) black holes are the densest bodies possible for a given mass. Since there is a limit to how much a body can be compressed, forces – whether gravitational, electric, centripetal or of any other type – cannot be arbitrary large.

Alternatively, it is possible to use another, equivalent statement as a basic principle:

▷ *There is a maximum power in nature:*

$$P \leqslant \frac{c^5}{4G} = 9.1 \cdot 10^{51}\,\mathrm{W}\,. \tag{238}$$

No power of any lamp, engine or explosion can exceed this value. The maximum power is realized when a (Schwarzschild) black hole is radiated away in the time that light takes to travel along a length corresponding to its diameter. We will see below precisely what black holes are and why they are connected to these limits.

The existence of a maximum force or power implies the full theory of general rela-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

tivity. In order to prove the correctness and usefulness of this approach, a sequence of arguments is required. The sequence is the same as for the establishment of the limit speed in special relativity. First of all, we have to gather all observational evidence for the claimed limit. Secondly, in order to establish the limit as a principle of nature, we have to show that general relativity follows from it. Finally, we have to show that the limit applies in all possible and imaginable situations. Any apparent paradoxes will need to be resolved.

These three steps structure this introduction to general relativity. We start the story by explaining the origin of the idea of a limiting value.

The force and power limits

In the nineteenth and twentieth centuries many physicists took pains to avoid the concept of force. Heinrich Hertz made this a guiding principle of his work, and wrote an influential textbook on classical mechanics without ever using the concept. The fathers of quantum theory, who all knew this text, then dropped the term 'force' completely from the vocabulary of microscopic physics. Meanwhile, the concept of 'gravitational force' was eliminated from general relativity by reducing it to a 'pseudo-force'. Force fell out of fashion.

Nevertheless, the maximum force principle does make sense, provided that we visualize it by means of the useful definition: *force is the flow of momentum per unit time*. Momentum cannot be created or destroyed. We use the term 'flow' to remind us that momentum, being a conserved quantity, can only change by inflow or outflow. In other words, change of momentum always takes place through some boundary surface. This fact is of central importance. Whenever we think about force at a point, we mean the momentum 'flowing' through a surface at that point. General relativity states this idea usually as follows: force keeps bodies from following geodesics. The mechanism underlying a measured force is not important. In order to have a concrete example to guide the discussion it can be helpful to imagine force as electromagnetic in origin. In fact, any type of force is possible.

The maximum force principle thus boils down to the following: if we imagine any physical surface (and cover it with observers), the integral of momentum flow through the surface (measured by all those observers) never exceeds a certain value. It does not matter how the surface is chosen, as long as it is physical, i.e., as long as we can fix observers* onto it.

This principle imposes a limit on muscles, the effect of hammers, the flow of material, the acceleration of massive bodies, and much more. No system can create, measure or experience a force above the limit. No particle, no galaxy and no bulldozer can exceed it.

The existence of a force limit has an appealing consequence. In nature, forces can be measured. Every measurement is a comparison with a standard. The force limit provides a *natural* unit of force which fits into the system of natural units** that Max Planck de-

* Observers in general relativity, like in special relativity, are massive physical systems that are small enough so that their influence on the system under observation is negligible.

** When Planck discovered the quantum of action, he had also noticed the possibility to define natural units. On a walk with his seven-year-old son in the forest around Berlin, he told him that he had made a discovery as important as the discovery of universal gravity.

Page 979

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 51 How to convince yourself and others that there is a maximum force $c^4/4G$ (or a maximum power $c^5/4G$) in nature

ISSUE	METHOD
Force values > $c^4/4G$ are not observed	check all observations
Force values > $c^4/4G$ are either non-local or not due to energy transport	check all observations
Force values > $c^4/4G$ cannot be produced	check all attempts
Force values > $c^4/4G$ cannot be imagined	solve all paradoxes
A maximum force value $c^4/4G$ is consistent	1 – show that all consequences, however weird, are confirmed by observation 2 – deduce the theory of general relativity from it and check it

rived from c, G and h (or $\hbar$). The maximum force thus provides a standard of force valid in every place and at every instant of time.

The limit value of $c^4/4G$ differs from Planck's proposed unit in two ways. First, the numerical factor is different (Planck had in mind the value c^4/G). Secondly, the force unit is a *limiting* value. In this respect, the maximum force plays the same role as the maximum speed. As we will see later on, this limit property is valid for all other Planck units as well, once the numerical factors have been properly corrected. The factor 1/4 has no deeper meaning: it is just the value that leads to the correct form of the field equations of general relativity. The factor 1/4 in the limit is also required to recover, in everyday situations, the inverse square law of universal gravitation. When the factor is properly taken into account, the maximum force (or power) is simply given by the (corrected) Planck energy divided by the (corrected) Planck length or Planck time.

Ref. 377
Page 1458
Page 491

The expression for the maximum force involves the speed of light c and the gravitational constant G; it thus qualifies as a statement on relativistic gravitation. The fundamental principle of special relativity states that speed v obeys $v \leqslant c$ for all observers. Analogously, the basic principle of general relativity states that in all cases force F and power P obey $F \leqslant c^4/4G$ and $P \leqslant c^5/4G$. It does not matter whether the observer measures the force or power while moving with high velocity relative to the system under observation, during free fall, or while being strongly accelerated. However, we will see that it is essential that the observer records values measured *at his own location* and that the observer is *realistic*, i.e., made of matter and not separated from the system by a horizon. These conditions are the same that must be obeyed by observers measuring velocity in special relativity.

Since physical power is force times speed, and since nature provides a speed limit,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the force bound and the power bound are equivalent. We have already seen that force
Page 452 and power appear together in the definition of 4-force; we can thus say that the upper bound is valid for every component of a force, as well as for its magnitude. The power bound limits the output of car and motorcycle engines, lamps, lasers, stars, gravitational radiation sources and galaxies. It is equivalent to $1.2 \cdot 10^{49}$ horsepower. The maximum power principle states that there is no way to move or get rid of energy more quickly than that.

The power limit can be understood intuitively by noting that every engine produces *exhausts*, i.e., some matter or energy that is left behind. For a lamp, a star or an evaporating black hole, the exhausts are the emitted radiation; for a car or jet engine they are hot gases; for a water turbine the exhaust is the slowly moving water leaving the turbine; for a rocket it is the matter ejected at its back end; for a photon rocket or an electric motor it is electromagnetic energy. Whenever the power of an engine gets close to the limit value, the exhausts increase dramatically in mass–energy. For extremely high exhaust masses, the gravitational attraction from these exhausts – even if they are only radiation – prevents further acceleration of the engine with respect to them. The maximum power principle thus expresses that there is a built-in braking mechanism in nature; this braking mechanism is gravity.

Yet another, equivalent limit appears when the maximum power is divided by c^2.

▷ *There is a maximum rate of mass change in nature:*

$$\frac{\mathrm{d}m}{\mathrm{d}t} \leqslant \frac{c^3}{4G} = 1.0 \cdot 10^{35}\,\mathrm{kg/s}\,. \tag{239}$$

This bound imposes a limit on pumps, jet engines and fast eaters. Indeed, the rate of flow of water or any other material through tubes is limited. The mass flow limit is obviously equivalent to either the force or the power limit.

The claim of a maximum force, power or mass change in nature seems almost too fantastic to be true. Our first task is therefore to check it empirically as thoroughly as we can.

The experimental evidence

Like the maximum speed principle, the maximum force principle must first of all be checked experimentally. Michelson spent a large part of his research life looking for possible changes in the value of the speed of light. No one has yet dedicated so much effort to testing the maximum force or power. However, it is straightforward to confirm that no experiment, whether microscopic, macroscopic or astronomical, has ever measured force values larger than the stated limit. Many people have claimed to have produced speeds larger than that of light. So far, nobody has ever claimed to have produced a force larger than the limit value.

The large accelerations that particles undergo in collisions inside the Sun, in the most powerful accelerators or in reactions due to cosmic rays correspond to force values much smaller than the force limit. The same is true for neutrons in neutron stars, for quarks inside protons, and for all matter that has been observed to fall towards black holes. Furthermore, the search for space-time singularities, which would allow forces to achieve or

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

exceed the force limit, has been fruitless.

In the astronomical domain, all forces between stars or galaxies are below the limit value, as are the forces in their interior. Not even the interactions between any two halves of the universe exceed the limit, whatever physically sensible division between the two halves is taken. (The meaning of 'physically sensible division' will be defined below; for divisions that are *not* sensible, exceptions to the maximum force claim *can* be constructed. You might enjoy searching for such an exception.)

Page 489

Challenge 752 s

Astronomers have also failed to find any region of space-time whose curvature (a concept to be introduced below) is large enough to allow forces to exceed the force limit. Indeed, none of the numerous recent observations of black holes has brought to light forces larger than the limit value or objects smaller than the corresponding black hole radii. Observations have also failed to find a situation that would allow a rapid observer to observe a force value that exceeds the limit due to the relativistic boost factor.

The power limit can also be checked experimentally. It turns out that the power – or luminosity – of stars, quasars, binary pulsars, gamma ray bursters, galaxies or galaxy clusters can indeed be a sizeable fraction of the power limit. However, no violation of the limit has ever been observed. In fact, the sum of all light output from all stars in the universe does not exceed the limit. Similarly, even the brightest sources of gravitational waves, merging black holes, do not exceed the power limit. Only the brightness of evaporating black holes in their final phase could equal the limit. But so far, none has ever been observed. (The fact that single sources in the universe can approach the power limit, while the universe also has to obey it, is the power paradox. More about it below.)

Ref. 379

Page 490

Similarly, all observed mass flow rates are orders of magnitude below the corresponding limit. Even physical systems that are mathematical analogues of black holes – for example, silent acoustical black holes or optical black holes – do not invalidate the force and power limits that hold in the corresponding systems.

The experimental situation is somewhat disappointing. Experiments do not contradict the limit values. But neither do the data do much to confirm them. The reason is the lack of horizons in everyday life and in experimentally accessible systems. The maximum speed at the basis of special relativity is found almost everywhere; maximum force and maximum power are found almost nowhere. Below we will propose some dedicated tests of the limits that could be performed in the future.

Page 495

Deducing general relativity*

In order to establish the maximum force and power limits as fundamental physical principles, it is not sufficient to show that they are consistent with what we observe in nature. It is necessary to show that they imply the complete theory of general relativity. (This section is only for readers who already know the field equations of general relativity. Other readers may skip to the next section.)

Page 481

In order to derive the theory of relativity we need to study those systems that *realize* the limit under scrutiny. In the case of the special theory of relativity, the main system that realizes the limit speed is light. For this reason, light is central to the exploration of special relativity. In the case of general relativity, the systems that realize the

* This section can be skipped at first reading. (The mentioned proof dates from December 2003.)

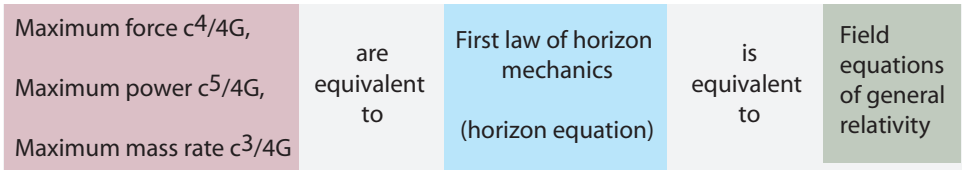

FIGURE 269 Showing the equivalence of the maximum force or power with the field equations of general relativity

limit are less obvious. We note first that a maximum force (or power) cannot be realized throughout a *volume* of space. If this were possible, a simple boost* could transform the force (or power) to a higher value. Therefore, nature can realize maximum force and power only on surfaces, not volumes. In addition, these surfaces must be unattainable. These unattainable surfaces are basic to general relativity; they are called *horizons*. Maximum force and power only appear on horizons. We have encountered horizons in special relativity, where they were defined as surfaces that impose limits to observation. (Note the contrast with everyday life, where a horizon is only a line, not a surface.) The present definition of a horizon as a surface of maximum force (or power) is equivalent to the definition as a surface beyond which no signal may be received. In both cases, a horizon is a surface beyond which interaction is impossible.

Ref. 377

Page 465

The connection between horizons and the maximum force is a central point of relativistic gravity. It is as important as the connection between light and the maximum speed in special relativity. In special relativity, we showed that the fact that light speed is the maximum speed in nature implies the Lorentz transformations. In general relativity, we will now prove that the maximum force in nature, which we can call the *horizon force*, implies the field equations of general relativity. To achieve this aim, we start with the realization that all horizons have an energy flow across them. The flow depends on the horizon curvature, as we will see. This connection implies that horizons cannot be planes, as an infinitely extended plane would imply an infinite energy flow.

The deduction of the equations of general relativity has only two steps, as shown in Figure 269. In the first step, we show that the maximum force or power principle implies the first 'law' of horizon mechanics. In the second step, we show that the first 'law' implies the field equations of general relativity.

The simplest finite horizon is a static sphere, corresponding to a Schwarzschild black hole. A spherical horizon is characterized by its radius of curvature R, or equivalently, by its surface gravity a; the two quantities are related by $2aR = c^2$. Now, the energy flowing through any horizon is always finite in extension, when measured along the propagation direction. One can thus speak more specifically of an energy pulse. Any energy pulse through a horizon is thus characterized by an energy E and a proper length L. When the energy pulse flows perpendicularly through a horizon, the rate of momentum change, or force, for an observer at the horizon is

$$F = \frac{E}{L} \,. \tag{240}$$

* A *boost* was defined in special relativity as a change of viewpoint to a second observer *moving* in relation to the first.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Our goal is to show that the existence of a maximum force implies general relativity. Now, maximum force is realized on horizons. We thus need to insert the maximum possible values on both sides of equation (240) and to show that general relativity follows.

Using the maximum force value and the area $4\pi R^2$ for a spherical horizon we get

$$\frac{c^4}{4G} = \frac{E}{LA} 4\pi R^2 \,. \tag{241}$$

The fraction E/A is the energy per area flowing through any area A that is part of a horizon. The insertion of the maximum values is complete when one notes that the length L of the energy pulse is limited by the radius R. The limit $L \leqslant R$ follows from geometrical considerations: seen from the concave side of the horizon, the pulse must be shorter than the radius of curvature. An independent argument is the following. The length L of an object accelerated by a is limited, by special relativity, by $L \leqslant c^2/2a$. Special relativity already shows that this limit is related to the appearance of a horizon. Together with relation (241), the statement that horizons are surfaces of maximum force leads to the following important relation for static, spherical horizons:

Ref. 380

$$E = \frac{c^2}{8\pi G} a A \,. \tag{242}$$

This *horizon equation* relates the energy flow E through an area A of a spherical horizon with surface gravity a. It states that the energy flowing through a horizon is limited, that this energy is proportional to the area of the horizon, and that the energy flow is proportional to the surface gravity. (The horizon equation is also called the *first law of black hole mechanics* or the *first law of horizon mechanics*.)

Ref. 381

The above derivation also yields the intermediate result

$$E \leqslant \frac{c^4}{16\pi G} \frac{A}{L} \,. \tag{243}$$

This form of the horizon equation states more clearly that no surface other than a horizon can achieve the maximum energy flow, when the area and pulse length (or surface gravity) are given. No other domain of physics makes comparable statements: they are intrinsic to the theory of gravitation.

An alternative derivation of the horizon equation starts with the emphasis on power instead of on force, using $P = E/T$ as the initial equation.

It is important to stress that the horizon equations (242) and (243) follow from only two assumptions: first, there is a maximum speed in nature, and secondly, there is a maximum force (or power) in nature. No specific theory of gravitation is assumed. The horizon equation might even be testable experimentally, as argued below. (We also note that the horizon equation – or, equivalently, the force or power limit – implies a maximum mass change rate in nature given by $\mathrm{d}m/\mathrm{d}t \leqslant c^3/4G$.)

Next, we have to generalize the horizon equation from static and spherical horizons to general horizons. Since the maximum force is assumed to be valid for *all* observers, whether inertial or accelerating, the generalization is straightforward. For a horizon that

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

is irregularly curved or time-varying the horizon equation becomes

$$\delta E = \frac{c^2}{8\pi G}\, a\, \delta A \,. \tag{244}$$

This differential relation – it might be called the *general horizon equation* – is valid for any horizon. It can be applied separately for every piece δA of a dynamic or spatially changing horizon. The general horizon equation (244) has been known to be equivalent to general relativity at least since 1995, when this equivalence was (implicitly) shown by Jacobson. We will show that the differential horizon equation has the same role for general relativity as the equation $\mathrm{d}x = c\,\mathrm{d}t$ has for special relativity. From now on, when we speak of the horizon equation, we mean the general, differential form (244) of the relation.

Ref. 382

It is instructive to restate the behaviour of energy pulses of length L in a way that holds for any surface, even one that is not a horizon. Repeating the above derivation, one gets

$$\frac{\delta E}{\delta A} \leqslant \frac{c^4}{16\pi G}\,\frac{1}{L} \,. \tag{245}$$

Equality is only realized when the surface A is a horizon. In other words, whenever the value $\delta E/\delta A$ in a physical system approaches the right-hand side, a horizon starts to form. This connection will be essential in our discussion of apparent counter-examples to the limit principles.

If one keeps in mind that on a horizon the pulse length L obeys $L \leqslant c^2/2a$, it becomes clear that the general horizon equation is a consequence of the maximum force $c^4/4G$ or the maximum power $c^5/4G$. In addition, the horizon equation takes also into account maximum speed, which is at the origin of the relation $L \leqslant c^2/2a$. The horizon equation thus follows purely from these two limits of nature.

The remaining part of the argument is simply the derivation of general relativity from the general horizon equation. This derivation was implicitly provided by Jacobson, and the essential steps are given in the following paragraphs. (Jacobson did not stress that his derivation was valid also for continuous space-time, or that his argument could also be used in classical general relativity.) To see the connection between the general horizon equation (244) and the field equations, one only needs to generalize the general horizon equation to general coordinate systems and to general directions of energy–momentum flow. This is achieved by introducing tensor notation that is adapted to curved space-time.

Ref. 382

To generalize the general horizon equation, one introduces the general surface element $\mathrm{d}\Sigma$ and the local boost Killing vector field k that generates the horizon (with suitable norm). Jacobson uses these two quantities to rewrite the left-hand side of the general horizon equation (244) as

$$\delta E = \int T_{ab} k^a \mathrm{d}\Sigma^b \,, \tag{246}$$

where T_{ab} is the energy–momentum tensor. This expression obviously gives the energy at the horizon for arbitrary coordinate systems and arbitrary energy flow directions.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Jacobson's main result is that the factor $a\,\delta A$ in the right hand side of the general horizon equation (244) can be rewritten, making use of the (purely geometric) Raychaudhuri equation, as

$$a\,\delta A = c^2 \int R_{ab} k^a \mathrm{d}\Sigma^b \,, \tag{247}$$

where R_{ab} is the Ricci tensor describing space-time curvature. This relation describes how the local properties of the horizon depend on the local curvature.

Combining these two steps, the general horizon equation (244) becomes

$$\int T_{ab} k^a \mathrm{d}\Sigma^b = \frac{c^4}{8\pi G} \int R_{ab} k^a \mathrm{d}\Sigma^b \,. \tag{248}$$

Jacobson then shows that this equation, together with local conservation of energy (i.e., vanishing divergence of the energy–momentum tensor) can only be satisfied if

$$T_{ab} = \frac{c^4}{8\pi G} \left(R_{ab} - (\frac{R}{2} + \Lambda) g_{ab} \right) \,, \tag{249}$$

where R is the Ricci scalar and Λ is a constant of integration the value of which is not determined by the problem. The above equations are the full field equations of general relativity, including the cosmological constant Λ. The field equations thus follow from the horizon equation. They are therefore shown to be valid at horizons.

Since it is possible, by choosing a suitable coordinate transformation, to position a horizon at any desired space-time point, the field equations must be valid over the whole of space-time. This observation completes Jacobson's argument. Since the field equations follow, via the horizon equation, from the maximum force principle, we have also shown that at every space-time point in nature the same maximum force holds: the value of the maximum force is an invariant and a constant of nature.

In other words, the field equations of general relativity are a direct consequence of the limit on energy flow at horizons, which in turn is due to the existence of a maximum force (or power). In fact, as Jacobson showed, the argument works in both directions. Maximum force (or power), the horizon equation, and general relativity are equivalent.

In short, *the maximum force principle is a simple way to state that, on horizons, energy flow is proportional to area and surface gravity*. This connection makes it possible to deduce the full theory of general relativity. In particular, a maximum force value is sufficient to tell space-time how to curve. We will explore the details of this relation shortly. Note that if no force limit existed in nature, it would be possible to 'pump' any desired amount of energy through a given surface, including any horizon. In this case, the energy flow would not be proportional to area, horizons would not have the properties they have, and general relativity would not hold. We thus get an idea how the maximum flow of energy, the maximum flow of momentum and the maximum flow of mass are all connected to horizons. The connection is most obvious for black holes, where the energy, momentum or mass are those falling into the black hole.

Page 606

By the way, since the derivation of general relativity from the maximum force principle or from the maximum power principle is now established, we can rightly call these

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

limits *horizon force* and *horizon power*. Every experimental or theoretical confirmation of the field equations indirectly confirms their existence.

Space-time is curved

Imagine two observers who start moving parallel to each other and who continue straight ahead. If after a while they discover that they are not moving parallel to each other any more, then they can deduce that they have moved on a curved surface (try it!) or in a curved space. In particular, this happens near a horizon. The derivation above showed that a finite maximum force implies that all horizons are curved; the curvature of horizons in turn implies the curvature of space-time. If nature had only flat horizons, there would be no space-time curvature. The existence of a maximum force implies that space-time is curved.

Challenge 753 s

A horizon so strongly curved that it forms a closed boundary, like the surface of a sphere, is called a black hole. We will study black holes in detail below. The main property of a black hole, like that of any horizon, is that it is impossible to detect what is 'behind' the boundary.*

Page 604

The analogy between special and general relativity can thus be carried further. In special relativity, maximum speed implies $dx = c\,dt$, and the change of time depends on the observer. In general relativity, maximum force (or power) implies the horizon equation $\delta E = \frac{c^2}{8\pi G}\, a\, \delta A$ and the observation that space-time is curved.

The maximum force (or power) thus has the same double role in general relativity as the maximum speed has in special relativity. In special relativity, the speed of light is the maximum speed; it is also the proportionality constant that connects space and time, as the equation $dx = c\,dt$ makes apparent. In general relativity, the horizon force is the maximum force; it also appears (with a factor 2π) in the field equations as the proportionality constant connecting energy and curvature. The maximum force thus describes both the elasticity of space-time and – if we use the simple image of space-time as a medium – the maximum tension to which space-time can be subjected. This double role of a material constant as proportionality factor and as limit value is well known in materials science.

Does this analogy make you think about aether? Do not worry: physics has no need for the concept of aether, because it is indistinguishable from vacuum. General relativity does describe the vacuum as a sort of material that can be deformed and move.

Page 757

Why is the maximum force also the proportionality factor between curvature and energy? Imagine space-time as an elastic material. The elasticity of a material is described by a numerical material constant. The simplest definition of this material constant is the ratio of stress (force per area) to strain (the proportional change of length). An exact definition has to take into account the geometry of the situation. For example, the shear modulus G (or μ) describes how difficult it is to move two parallel surfaces of a material against each other. If the force F is needed to move two parallel surfaces of area A and length l against each other by a distance Δl, one defines the shear modulus G by

$$\frac{F}{A} = G\frac{\Delta l}{l} \,. \tag{250}$$

* Analogously, in special relativity it is impossible to detect what moves faster than the light barrier.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The shear modulus for metals and alloys ranges between 25 and 80 GPa. The continuum theory of solids shows that for any crystalline solid without any defect (a 'perfect' solid) there is a so-called theoretical shear stress: when stresses higher than this value are applied, the material breaks. The theoretical shear stress, in other words, the maximum stress in a material, is given by

$$G_{\text{tss}} = \frac{G}{2\pi} \,. \tag{251}$$

The maximum stress is thus essentially given by the shear modulus. This connection is similar to the one we found for the vacuum. Indeed, imagining the vacuum as a material
Ref. 383 that can be bent is a helpful way to understand general relativity. We will use it regularly in the following.

What happens when the vacuum is stressed with the maximum force? Is it also torn apart like a solid? Yes: in fact, when vacuum is torn apart, particles appear. We will find out more about this connection later on: since particles are quantum entities, we need to study quantum theory first, before we can describe the effect in the last part of our mountain ascent.

Conditions of validity of the force and power limits

The maximum force value is valid only under certain assumptions. To clarify this point, we can compare it to the maximum speed. The speed of light (in vacuum) is an upper limit for motion of systems with *momentum* or *energy* only. It can, however, be exceeded for motions of non-material points. Indeed, the cutting point of a pair of scissors, a laser light spot on the Moon, or the group velocity or phase velocity of wave groups can exceed
Page 435 the speed of light. In addition, the speed of light is a limit only if measured *near* the moving mass or energy: the Moon moves faster than light if one turns around one's axis in a second; distant points in a Friedmann universe move apart from each other with speeds larger than the speed of light. Finally, the observer must be *realistic*: the observer must be made of matter and energy, and thus move more slowly than light, and must be able to observe the system. No system moving at or above the speed of light can be an
Ref. 384 observer.

The same three conditions apply in general relativity. In particular, relativistic gravity forbids point-like observers and test masses: they are not realistic. Surfaces moving faster than light are also not realistic. In such cases, counter-examples to the maximum force
Challenge 754 s claim can be found. Try and find one – many are possible, and all are fascinating. We will explore some of the most important ones below.

Another point should be stressed. General relativity implies a maximum power and force. The reverse, the deduction of general relativity's field equations from the maximum power of force, is correct only under the assumption that gravity is purely geometric. This is the essential statement of general relativity. If the mechanism of gravity would be based on other fields, such as hitherto unknown particles, the equivalence between gravity and a maximum force would not be given.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

GEDANKEN EXPERIMENTS AND PARADOXES ABOUT THE FORCE LIMIT

> Wenn eine Idee am Horizonte eben aufgeht, ist gewöhnlich die Temperatur der Seele dabei sehr kalt. Erst allmählich entwickelt die Idee ihre Wärme, und am heissesten ist diese (das heisst sie tut ihre grössten Wirkungen), wenn der Glaube an die Idee schon wieder im Sinken ist.
>
> Friedrich Nietzsche*

The last, but central, step in our discussion of the force limit is the same as in the discussion of the speed limit. We need to show that any *imaginable* experiment – not only any real one – satisfies the hypothesis. Following a tradition dating back to the early twentieth century, such an imagined experiment is called a *Gedanken experiment*, from the German Gedankenexperiment, meaning 'thought experiment'.

In order to dismiss all imaginable attempts to exceed the maximum speed, it is sufficient to study the properties of velocity addition and the divergence of kinetic energy near the speed of light. In the case of maximum force, the task is much more involved. Indeed, stating a maximum force, a maximum power and a maximum mass change easily provokes numerous attempts to contradict them. We will now discuss some of these.

* *

The brute force approach. The simplest attempt to exceed the force limit is to try to accelerate an object with a force larger than the maximum value. Now, acceleration implies the transfer of energy. This transfer is limited by the horizon equation (244) or the limit (245). For any attempt to exceed the force limit, the flowing energy results in the appearance of a horizon. But a horizon prevents the force from exceeding the limit, because it imposes a limit on interaction.

Page 468

We can explore this limit directly. In special relativity we found that the acceleration of an object is limited by its length. Indeed, at a distance given by $c^2/2a$ in the direction opposite to the acceleration a, a *horizon* appears. In other words, an accelerated body breaks, at the latest, at that point. The force F on a body of mass M and radius R is thus limited by

$$F \leqslant \frac{M}{2R}\, c^2 \,. \tag{252}$$

It is straightforward to add the (usually small) effects of gravity. To be observable, an accelerated body must remain *larger* than a black hole; inserting the corresponding radius $R = 2GM/c^2$ we get the force limit (237). *Dynamic* attempts to exceed the force limit thus fail.

* *

The rope attempt. We can also try to generate a higher force in a *static* situation, for

* 'When an idea is just rising on the horizon, the soul's temperature with respect to it is usually very cold. Only gradually does the idea develop its warmth, and it is hottest (which is to say, exerting its greatest influence) when belief in the idea is already once again in decline.' Friedrich Nietzsche (1844–1900), German philosopher and scholar. This is aphorism 207 – *Sonnenbahn der Idee* – from his text *Menschliches Allzumenschliches – Der Wanderer und sein Schatten*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

example by pulling two ends of a rope in opposite directions. We assume for simplicity that an unbreakable rope exists. Any rope works because the potential energy between its atoms can produce high forces between them. To produce a rope force exceeding the limit value, we need to store large (elastic) energy in the rope. This energy must enter from the ends. When we increase the tension in the rope to higher and higher values, more and more (elastic) energy must be stored in smaller and smaller distances. To exceed the force limit, we would need to add more energy per distance and area than is allowed by the horizon equation. A horizon thus inevitably appears. But there is no way to stretch a rope across a horizon, even if it is unbreakable. A horizon leads either to the breaking of the rope or to its detachment from the pulling system. Horizons thus make it impossible to generate forces larger than the force limit. In fact, the assumption of infinite wire strength is unnecessary: the force limit cannot be exceeded even if the strength of the wire is only finite.

We note that it is not important whether an applied force pulls – as for ropes or wires – or pushes. In the case of *pushing* two objects against each other, an attempt to increase the force value without end will equally lead to the formation of a horizon, due to the limit provided by the horizon equation. By definition, this happens precisely at the force limit. As there is no way to use a horizon to push (or pull) on something, the attempt to achieve a higher force ends once a horizon is formed. Static forces cannot exceed the limit value.

* *

The braking attempt. A force limit provides a maximum momentum change per time. We can thus search for a way to *stop* a moving physical system so abruptly that the maximum force might be exceeded. The non-existence of rigid bodies in nature, already known from special relativity, makes a completely sudden stop impossible; but special relativity on its own provides no lower limit to the stopping time. However, the inclusion of gravity does. Stopping a moving system implies a transfer of energy. The energy flow per area cannot exceed the value given by the horizon equation. Thus one cannot exceed the force limit by stopping an object.

Page 468

Similarly, if a rapid system is *reflected* instead of stopped, a certain amount of energy needs to be transferred and stored for a short time. For example, when a tennis ball is reflected from a large wall its momentum changes and a force is applied. If many such balls are reflected at the same time, surely a force larger than the limit can be realized? It turns out that this is impossible. If one attempted it, the energy flow at the wall would reach the limit given by the horizon equation and thus create a horizon. In that case, no reflection is possible any more. So the limit cannot be exceeded.

* *

The classical radiation attempt. Instead of systems that pull, push, stop or reflect *matter*, we can explore systems where *radiation* is involved. However, the arguments hold in exactly the same way, whether photons, gravitons or other particles are involved. In particular, mirrors, like walls, are limited in their capabilities.

It is also impossible to create a force larger than the maximum force by concentrating a large amount of light onto a surface. The same situation as for tennis balls arises: when the limit value E/A given by the horizon equation (245) is reached, a horizon appears

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

that prevents the limit from being broken.

* *

The brick attempt. The force and power limits can also be tested with more concrete Gedanken experiments. We can try to exceed the force limit by stacking weight. But even building an infinitely high brick tower does not generate a sufficiently strong force on its foundations: integrating the weight, taking into account its decrease with height, yields a finite value that cannot reach the force limit. If we continually increase the mass density of the bricks, we need to take into account that the tower and the Earth will change into a black hole. And black holes, as mentioned above, do not allow the force limit to be exceeded.

* *

The boost attempt. A boost can apparently be chosen in such a way that a force value F in one frame is transformed into any desired value F' in another frame. However, this result is not physical. To be more concrete, imagine a massive observer, measuring the value F, at rest with respect to a large mass, and a second observer moving towards the charged mass with relativistic speed, measuring the value F'. Both observers can be thought as being as small as desired. If one transforms the force field at rest F applying the Lorentz transformations, the force F' for the moving observer can reach extremely high values, as long as the speed is high enough. However, a force must be measured by an observer located at the specific point. One has thus to check what happens when the rapid observer moves towards the region where the force is supposed to exceed the force limit. Suppose the observer has a mass m and a radius r. To be an observer, it must be larger than a black hole; in other words, its radius must obey $r > 2Gm/c^2$, implying that the observer has a non-vanishing size. When the observer dives into the force field surrounding the sphere, there will be an energy flow E towards the observer determined by the transformed field value and the crossing area of the observer. This interaction energy can be made as small as desired, by choosing a sufficiently small observer, but the energy is never zero. When the moving observer approaches the large massive charge, the interaction energy increases. Before the observer arrives at the point where the force was supposed to be higher than the force limit, the interaction energy will reach the horizon limits (244) or (245) for the observer. Therefore, a horizon appears and the moving observer is prevented from observing anything at all, in particular any value above the horizon force.

Ref. 385

The same limitation appears when electrical or other interactions are studied using a test observer that is charged. In summary, boosts cannot beat the force limit.

* *

The divergence attempt. The force on a test mass m at a radial distance d from a Schwarzschild black hole (for $\Lambda = 0$) is given by

Ref. 379

$$F = \frac{GMm}{d^2\sqrt{1 - \frac{2GM}{dc^2}}} \,. \tag{253}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In addition, the inverse square law of universal gravitation states that the force between two masses m and M is

$$F = \frac{GMm}{d^2} \,. \tag{254}$$

Both expressions can take any value; this suggest that no maximum force limit exists.

A detailed investigation shows that the maximum force still holds. Indeed, the force in the two situations diverges only for non-physical point-like masses. However, the maximum force implies a minimum approach distance to a mass m given by

$$d_{\min} = \frac{2Gm}{c^2} \,. \tag{255}$$

The minimum approach distance – in simple terms, this would be the corresponding black hole radius – makes it impossible to achieve zero distance between two masses or between a horizon and a mass. This implies that a mass can never be point-like, and that there is a (real) minimum approach distance, proportional to the mass. If this minimum approach distance is introduced in equations (253) and (254), one gets

$$F = \frac{c^4}{4G} \frac{Mm}{(M+m)^2} \frac{1}{\sqrt{1 - \frac{M}{M+m}}} \leqslant \frac{c^4}{4G} \tag{256}$$

and

$$F = \frac{c^4}{4G} \frac{Mm}{(M+m)^2} \leqslant \frac{c^4}{4G} . \tag{257}$$

The maximum force value is thus never exceeded, as long as we take into account the size of observers.

* *

The consistency problem. If observers cannot be point-like, one might question whether it is still correct to apply the original definition of momentum change or energy change as the integral of values measured by observers attached to a given surface. In general relativity, observers cannot be point-like, but they can be as small as desired. The original definition thus remains applicable when taken as a limit procedure for ever-decreasing observer size. Obviously, if quantum theory is taken into account, this limit procedure comes to an end at the Planck length. This is not an issue for general relativity, as long as the typical dimensions in the situation are much larger than this value.

* *

The quantum problem. If quantum effects are neglected, it is possible to construct surfaces with sharp angles or even fractal shapes that overcome the force limit. However, such surfaces are not physical, as they assume that lengths smaller than the Planck length can be realized or measured. The condition that a surface be physical implies that it must have an intrinsic indeterminacy given by the Planck length. A detailed study shows that quantum effects do not allow the horizon force to be exceeded.

* *

The relativistically extreme observer attempt. Any extreme observer, whether in rapid inertial or in accelerated motion, has no chance to beat the limit. In classical physics we are used to thinking that the interaction necessary for a measurement can be made as small as desired. This statement, however, is not valid for all observers; in particular, extreme observers cannot fulfil it. For them, the measurement interaction is large. As a result, a horizon forms that prevents the limit from being exceeded.

* *

The microscopic attempt. We can attempt to exceed the force limit by accelerating a small particle as strongly as possible or by colliding it with other particles. High forces do indeed appear when two high energy particles are smashed against each other. However, if the combined energy of the two particles became high enough to challenge the force limit, a horizon would appear before they could get sufficiently close.

In fact, quantum theory gives exactly the same result. Quantum theory by itself al-
Ref. 386 ready provides a limit to acceleration. For a particle of mass m it is given by

$$a \leqslant \frac{2mc^3}{\hbar} \,. \tag{258}$$

Here, $\hbar = 1.1 \cdot 10^{-34}$ Js is the quantum of action, a fundamental constant of nature. In particular, this acceleration limit is satisfied in particle accelerators, in particle collisions and in pair creation. For example, the spontaneous generation of electron–positron pairs in intense electromagnetic fields or near black hole horizons does respect the limit (258). Inserting the maximum possible mass for an elementary particle, namely the (corrected)
Page 1469 Planck mass, we find that equation (258) then states that the horizon force is the upper bound for elementary particles.

* *

The compaction attempt. Are black holes really the most dense form of matter or energy? The study of black hole thermodynamics shows that mass concentrations with higher
Ref. 379 density than black holes would contradict the principles of thermodynamics. In black hole thermodynamics, surface and entropy are related: reversible processes that reduce entropy could be realized if physical systems could be compressed to smaller values than the black hole radius. As a result, the size of a black hole is the limit size for a mass in nature. Equivalently, the force limit cannot be exceeded in nature.

* *

The force addition attempt. In special relativity, composing velocities by a simple vector addition is not possible. Similarly, in the case of forces such a naive sum is incorrect; any attempt to add forces in this way would generate a horizon. If textbooks on relativity had explored the behaviour of force vectors under addition with the same care with which they explored that of velocity vectors, the force bound would have appeared much earlier in the literature. (Obviously, general relativity is required for a proper treatment.)

* *

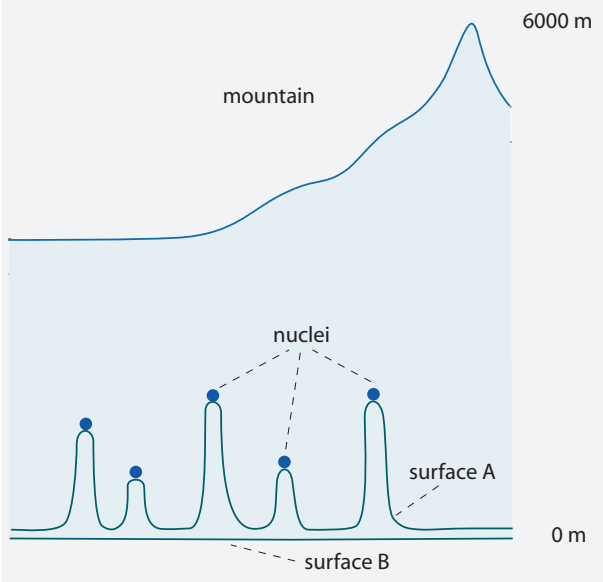

FIGURE 270 The mountain attempt to exceed the maximum mass flow value

Challenge 756 r Can you propose and resolve another attempt to exceed the force or power limit?

GEDANKEN EXPERIMENTS WITH THE POWER LIMIT AND THE MASS FLOW LIMIT

Like the force bound, the power bound must be valid for all *imaginable* systems. Here are some attempts to refute it.

* *

The cable-car attempt. Imagine an engine that accelerates a mass with an unbreakable and massless wire (assuming that such a wire could exist). As soon as the engine reached the power bound, either the engine or the exhausts would reach the horizon equation. When a horizon appears, the engine cannot continue to pull the wire, as a wire, even an infinitely strong one, cannot pass a horizon. The power limit thus holds whether the engine is mounted inside the accelerating body or outside, at the end of the wire pulling it.

* *

The mountain attempt. It is possible to define a surface that is so strangely bent that it passes *just below* every nucleus of every atom of a mountain, like the surface A in Figure 270. All atoms of the mountain above sea level are then *just above* the surface, barely touching it. In addition, imagine that this surface is moving *upwards* with almost the speed of light. It is not difficult to show that the mass flow through this surface is higher than the mass flow limit. Indeed, the mass flow limit $c^3/4G$ has a value of about 10^{35} kg/s. In a time of 10^{-22} s, the diameter of a nucleus divided by the speed of light, only 10^{13} kg need to flow through the surface: that is the mass of a mountain.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

This surface seems to provide a counter-example to the limit. However, a closer look shows that this is not the case. The problem is the expression 'just below'. Nuclei are quantum particles and have an indeterminacy in their position; this indeterminacy is essentially the nucleus–nucleus distance. As a result, in order to be sure that the surface of interest has all atoms *above* it, the shape cannot be that of surface A in Figure 270. It must be a flat plane that remains below the whole mountain, like surface B in the figure. However, a flat surface beneath a mountain does not allow the mass change limit to be exceeded.

* *

The multiple atom attempt. One can imagine a number of atoms equal to the number of the atoms of a mountain that all lie with large spacing (roughly) in a single plane. Again, the plane is moving upwards with the speed of light. But also in this case the indeterminacy in the atomic positions makes it impossible to say that the mass flow limit has been exceeded.

* *

The multiple black hole attempt. Black holes are typically large and the indeterminacy in their position is thus negligible. The mass limit $c^3/4G$, or power limit $c^5/4G$, corresponds to the flow of a single black hole moving through a plane at the speed of light. Several black holes crossing a plane together at just under the speed of light thus seem to beat the limit. However, the surface has to be physical: an observer must be possible on each of its points. But no observer can cross a black hole. A black hole thus effectively punctures the plane surface. No black hole can ever be said to cross a plane surface; even less so a multiplicity of black holes. The limit remains valid.

* *

The multiple neutron star attempt. The mass limit seems to be in reach when several neutron stars (which are slightly less dense than a black hole of the same mass) cross a plane surface at the same time, at high speed. However, when the speed approaches the speed of light, the crossing time for points far from the neutron stars and for those that actually cross the stars differ by large amounts. Neutron stars that are almost black holes cannot be crossed in a short time in units of a coordinate clock that is located far from the stars. Again, the limit is not exceeded.

* *

The luminosity attempt. The existence of a maximum luminosity bound has been dis-
Ref. 379 cussed by astrophysicists. In its full generality, the maximum bound on power, i.e., on energy per time, is valid for any energy flow *through any physical surface whatsoever*. The physical surface may even run across the whole universe. However, not even bringing together all lamps, all stars and all galaxies of the universe yields a surface which has a larger power output than the proposed limit.

The surface must be *physical*.* A surface is *physical* if an observer can be placed on each of its points. In particular, a physical surface may not cross a horizon, or have local

* It can also be called *physically sensible*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

detail finer than a certain minimum length. This minimum length will be introduced later on; it is given by the corrected Planck length. If a surface is not physical, it may provide a counter-example to the power or force limits. However, these counter-examples make no statements about nature. (*Ex falso quodlibet.*[*])

Page 1403
Challenge 757 s

* *

The many lamp attempt, or *power paradox*. An absolute power limit imposes a limit on the rate of energy transport through any imaginable surface. At first sight, it may seem that the combined power emitted by two radiation sources that each emit 3/4 of the maximum value should give 3/2 times that value. However, two such lamps would be so massive that they would form a black hole. No amount of radiation that exceeds the limit can leave. Again, since the horizon limit (245) is achieved, a horizon appears that swallows the light and prevents the force or power limit from being exceeded.

* *

The light concentration attempt. Another approach is to shine a powerful, short and spherical flash of light onto a spherical mass. At first sight it seems that the force and power limits can be exceeded, because light energy can be concentrated into small volumes. However, a high concentration of light energy forms a black hole or induces the mass to form one. There is no way to pump energy into a mass at a faster rate than that dictated by the power limit. In fact, it is impossible to group light sources in such a way that their total output is larger than the power limit. Every time the force limit is approached, a horizon appears that prevents the limit from being exceeded.

* *

The black hole attempt. One possible system in nature that actually *achieves* the power limit is the final stage of black hole evaporation. However, even in this case the power limit is not exceeded, but only equalled.

* *

The saturation attempt. If the universe already saturates the power limit, a new source would break it, or at least imply that another elsewhere must close down. Can you find the fallacy in this argument?

Challenge 758 ny

* *

The water flow attempt. One could try to pump water as rapidly as possible through a large tube of cross-section A. However, when a tube of length L filled with water flowing at speed v gets near to the mass flow limit, the gravity of the water *waiting* to be pumped through the area A will slow down the water that is being pumped through the area. The limit is again reached when the cross-section A turns into a horizon.

Checking that no system – from microscopic to astrophysical – ever exceeds the maximum power or maximum mass flow is a further test of general relativity. It may seem easy to find a counter-example, as the surface may run across the whole universe or envelop

[*] Anything can be deduced from a falsehood.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

any number of elementary particle reactions. However, no such attempt succeeds.

In summary, in all situations where the force, power or mass-flow limit is challenged, whenever the energy flow reaches the black hole mass–energy density in space or the corresponding momentum flow in time, an event horizon appears; this horizon makes it impossible to exceed the limits. All three limits are confirmed both in observation and in theory. Values exceeding the limits can neither be generated nor measured. Gedanken experiments also show that the three bounds are the tightest ones possible. Obviously, all three limits are open to future tests and to further Gedanken experiments. (If you can think of a good one, let the author know.)

Challenge 759 r

Hide and seek

The absence of horizons in everyday life is the *first* reason why the maximum force principle remained undiscovered for so long. Experiments in everyday life do not highlight the force or power limits. The *second* reason why the principle remained hidden is the erroneous belief in point particles. This is a theoretical reason. (Prejudices against the concept of force in general relativity have also been a factor.) The principle of maximum force – or of maximum power – has thus remained hidden for so long because of a 'conspiracy' of nature that hid it both from theorists and from experimentalists.

For a thorough understanding of general relativity it is essential to remember that point particles, point masses and point-like observers do not exist. They are approximations only applicable in Galilean physics or in special relativity. In general relativity, horizons prevent their existence. The habit of believing that the size of a system can be made as small as desired while keeping its mass constant prevents the force or power limit from being noticed.

An intuitive understanding of general relativity

> Wir leben zwar alle unter dem gleichen Himmel, aber wir haben nicht alle den gleichen Horizont.*
>
> Konrad Adenauer

The concepts of horizon force and horizon power can be used as the basis for a direct, intuitive approach to general relativity.

* *

What is gravity? Of the many possible answers we will encounter, we now have the first: gravity is the 'shadow' of the maximum force. Whenever we experience gravity as weak, we can remember that a different observer at the same point and time would experience the maximum force. Searching for the precise properties of that observer is a good exercise. Another way to put it: if there were no maximum force, gravity would not exist.

* *

The maximum force implies universal gravity. To see this, we study a simple planetary

* 'We all live under the same sky, but we do not have the same horizon.' Konrad Adenauer (1876–1967), West German Chancellor.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

system, i.e., one with small velocities and small forces. A simple planetary system of size L consists of a (small) satellite circling a central mass M at a radial distance $R = L/2$. Let a be the acceleration of the object. Small velocity implies the condition $aL \ll c^2$, deduced from special relativity; small force implies $\sqrt{4GMa} \ll c^2$, deduced from the force limit. These conditions are valid for the system as a whole and for all its components. Both expressions have the dimensions of speed squared. Since the system has only one characteristic speed, the two expressions $aL = 2aR$ and $\sqrt{4GMa}$ must be proportional, yielding

$$a = f\frac{GM}{R^2} \,, \tag{259}$$

where the numerical factor f must still be determined. To determine it, we study the escape velocity necessary to leave the central body. The escape velocity must be smaller than the speed of light for any body larger than a black hole. The escape velocity, derived from expression (259), from a body of mass M and radius R is given by $v_{\text{esc}}^2 = 2fGM/R$. The minimum radius R of objects, given by $R = 2GM/c^2$, then implies that $f = 1$. Therefore, for low speeds and low forces, the inverse square law describes the orbit of a satellite around a central mass.

* *

If empty space-time is elastic, like a piece of metal, it must also be able to oscillate. Any physical system can show oscillations when a deformation brings about a restoring force. We saw above that there is such a force in the vacuum: it is called gravitation. In other words, vacuum must be able to oscillate, and since it is extended, it must also be able to sustain waves. Indeed, gravitational waves are predicted by general relativity, as we will Page 525 see below.

* *

If curvature and energy are linked, the maximum speed must also hold for gravitational energy. Indeed, we will find that gravity has a finite speed of propagation. The inverse square law of everyday life cannot be correct, as it is inconsistent with any speed limit. More about the corrections induced by the maximum speed will become clear shortly. In addition, since gravitational waves are waves of massless energy, we would expect the Page 525 maximum speed to be their propagation speed. This is indeed the case, as we will see.

* *

A body cannot be denser than a (non-rotating) black hole of the same mass. The maximum force and power limits that apply to horizons make it impossible to squeeze mass into smaller horizons. The maximum force limit can therefore be rewritten as a limit for the size L of physical systems of mass m:

$$L \geqslant \frac{4Gm}{c^2} \,. \tag{260}$$

If we call twice the radius of a black hole its 'size', we can state that no physical system

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

of mass m is smaller than this value.* The size limit plays an important role in general relativity. The opposite inequality, $m \geqslant \sqrt{A/16\pi}\, c^2/G$, which describes the maximum 'size' of black holes, is called the *Penrose inequality* and has been proven for many physi-
Ref. 387, Ref. 388, Ref. 389 cally realistic situations. The Penrose inequality can be seen to imply the maximum force limit, and vice versa. The maximum force principle, or the equivalent minimum size of matter–energy systems, thus prevents the formation of naked singularities, and implies the validity of the so-called *cosmic censorship*.

* *

There is a power limit for all energy sources. In particular, the value $c^5/4G$ limits the luminosity of all gravitational sources. Indeed, all formulae for gravitational wave emission
Ref. 379 imply this value as an upper limit. Furthermore, numerical relativity simulations never exceed it: for example, the power emitted during the simulated merger of two black holes is below the limit.

* *

Perfectly plane waves do not exist in nature. Plane waves are of infinite extension. But neither electrodynamic nor gravitational waves can be infinite, since such waves would carry more momentum per time through a plane surface than is allowed by the force limit. The non-existence of plane gravitational waves also precludes the production of singularities when two such waves collide.

* *

In nature, there are no infinite forces. There are thus no naked singularities in nature. Horizons prevent the appearance of naked singularities. In particular, the big bang was *not* a singularity. The mathematical theorems by Penrose and Hawking that seem to imply the existence of singularities tacitly assume the existence of point masses – often in the form of 'dust' – in contrast to what general relativity implies. Careful re-evaluation of each such proof is necessary.

* *

The force limit means that space-time has a limited stability. The limit suggests that space-time can be torn into pieces. This is indeed the case. However, the way that this happens is not described by general relativity. We will study it in the last part of this text.

* *

The maximum force is the standard of force. This implies that the gravitational constant G is constant in space and time – or at least, that its variations across space and time
Ref. 390 cannot be detected. Present data support this claim to a high degree of precision.

* *

The maximum force principle implies that gravitational energy – as long as it can be defined – *falls* in gravitational fields in the same way as other type of energy. As a result,

* The maximum value for the mass to size limit is obviously equivalent to the maximum mass change given above.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 379 the maximum force principle predicts that the Nordtvedt effect vanishes. The Nordtvedt effect is a hypothetical periodical change in the orbit of the Moon that would appear if the gravitational energy of the Earth–Moon system did not fall, like other mass–energy, in the gravitational field of the Sun. Lunar range measurements have confirmed the absence of this effect.

* *

If horizons are surfaces, we can ask what their colour is. This question will be explored
Page 604 later on.

* *

Page 1468 Later on we will find that quantum effects cannot be used to exceed the force or power
Challenge 760 e limit. (Can you guess why?) Quantum theory also provides a limit to motion, namely a lower limit to action; however, this limit is independent of the force or power limit. (A dimensional analysis already shows this: there is no way to define an action by combinations of c and G.) Therefore, even the combination of quantum theory and general relativity does not help in overcoming the force or power limits.

An intuitive understanding of cosmology

A maximum power is the simplest possible explanation of Olbers' paradox. Power and luminosity are two names for the same observable. The sum of all luminosities in the universe is finite; the light and all other energy emitted by all stars, taken together, is finite. If one assumes that the universe is homogeneous and isotropic, the power limit $P \leqslant c^5/4G$ must be valid across any plane that divides the universe into two halves. The part of the universe's luminosity that arrives on Earth is then so small that the sky is dark at night. In fact, the actually measured luminosity is still smaller than this calculation, as a large part of the power is not visible to the human eye (since most of it is matter anyway). In other words, the night is dark because of nature's power limit. This explanation is *not* in contrast to the usual one, which uses the finite lifetime of stars, their finite density, their finite size, and the finite age and the expansion of the universe. In fact, the combination of all these usual arguments simply implies and repeats in more complex words that the power limit cannot be exceeded. However, this more simple explanation seems to be absent in the literature.

The existence of a maximum force in nature, together with homogeneity and isotropy, implies that the visible universe is of *finite size*. The opposite case would be an infinitely large, homogeneous and isotropic universe. But in that case, any two halves of the universe would attract each other with a force above the limit (provided the universe were sufficiently old). This result can be made quantitative by imagining a sphere whose centre lies at the Earth, which encompasses all the universe, and whose radius decreases with time almost as rapidly as the speed of light. The mass flow $\mathrm{d}m/\mathrm{d}t = \rho A v$ is predicted to reach the mass flow limit $c^3/4G$; thus one has

$$\frac{\mathrm{d}m}{\mathrm{d}t} = \rho_0 4\pi R_0^2 c = \frac{c^3}{4G} \quad , \tag{261}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 391 a relation also predicted by the Friedmann models. The precision measurements of the cosmic background radiation by the WMAP satellite confirm that the present-day total energy density ρ_0 (including dark matter and dark energy) and the horizon radius R_0 just reach the limit value. The maximum force limit thus predicts the observed size of the universe.

A finite power limit also suggests that a finite age for the universe can be deduced. Challenge 761 s Can you find an argument?

Experimental challenges for the third millennium

The lack of direct tests of the horizon force, power or mass flow is obviously due to the lack of horizons in the environment of all experiments performed so far. Despite the difficulties in reaching the limits, their values are observable and falsifiable.

In fact, the force limit might be tested with high-precision measurements in binary pulsars or binary black holes. Such systems allow precise determination of the positions of the two stars. The maximum force principle implies a relation between the position Ref. 377 error Δx and the energy error ΔE. For all systems one has

$$\frac{\Delta E}{\Delta x} \leqslant \frac{c^4}{4G} \,. \tag{262}$$

For example, a position error of 1 mm gives a mass error of below $3 \cdot 10^{23}$ kg. In everyday life, all measurements comply with this relation. Indeed, the left side is so much smaller than the right side that the relation is rarely mentioned. For a direct check, only systems which might achieve direct equality are interesting. Dual black holes or dual pulsars are such systems.

It might be that one day the amount of matter falling into some black hole, such as the one at the centre of the Milky Way, might be measured. The limit $\mathrm{d}m/\mathrm{d}t \leqslant c^3/4G$ could then be tested directly.

The power limit implies that the highest luminosities are only achieved when systems emit energy at the speed of light. Indeed, the maximum emitted power is only achieved when all matter is radiated away as rapidly as possible: the emitted power $P = Mc^2/(R/v)$ cannot reach the maximum value if the body radius R is larger than that of a black hole (the densest body of a given mass) or the emission speed v is lower than that of light. The sources with highest luminosity must therefore be of maximum density and emit entities without rest mass, such as gravitational waves, electromagnetic waves or (maybe) gluons. Candidates to detect the limit are black holes in formation, in evaporation or undergoing mergers.

A candidate surface that reaches the limit is the night sky. The night sky is a horizon. Provided that light, neutrino, particle and gravitational wave flows are added together, the limit $c^5/4G$ is predicted to be reached. If the measured power is smaller than the limit (as it seems to be at present), this might even give a hint about new particles yet to be discovered. If the limit were exceeded or not reached, general relativity would be shown to be incorrect. This might be an interesting future experimental test.

The power limit implies that a wave whose integrated intensity approaches the force limit cannot be plane. The power limit thus implies a limit on the product of intensity

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

I (given as energy per unit time and unit area) and the size (curvature radius) R of the front of a wave moving with the speed of light c:

$$4\pi R^2 I \leqslant \frac{c^5}{4G} \,. \tag{263}$$

Obviously, this statement is difficult to check experimentally, whatever the frequency and type of wave might be, because the value appearing on the right-hand side is extremely large. Possibly, future experiments with gravitational wave detectors, X-ray detectors, gamma ray detectors, radio receivers or particle detectors might allow us to test relation (263) with precision. (You might want to predict which of these experiments will confirm the limit first.)

Challenge 762 e

The lack of direct experimental tests of the force and power limits implies that *indirect tests* become particularly important. All such tests study the motion of matter or energy and compare it with a famous consequence of the force and power limits: the field equations of general relativity. This will be our next topic.

A summary of general relativity

There is a simple axiomatic formulation of general relativity: the horizon force $c^4/4G$ and the horizon power $c^5/4G$ are the highest possible force and power values. No contradicting observation is known. No counter-example has been imagined. General relativity follows from these limits. Moreover, the limits imply the darkness of the night and the finiteness of the size of the universe.

The principle of maximum force has obvious applications for the teaching of general relativity. The principle brings general relativity to the level of first-year university, and possibly to well-prepared secondary school, students: only the concepts of maximum force and horizon are necessary. Space-time curvature is a consequence of horizon curvature.

The concept of a maximum force points to an additional aspect of gravitation. The cosmological constant Λ is not fixed by the maximum force principle. (However, the principle does fix its sign to be positive.) Present measurements give the result $\Lambda \approx 10^{-52}\,/\mathrm{m}^2$. A positive cosmological constant implies the existence of a negative energy volume density $-\Lambda c^4/G$. This value corresponds to a negative pressure, as pressure and energy density have the same dimensions. Multiplication by the (numerically corrected) Planck area $2G\hbar/c^3$, the smallest area in nature, gives a force value

Challenge 763 ny

Page 587

Page 1466

$$F = 2\Lambda\hbar c = 0.60 \cdot 10^{-77}\,\mathrm{N} \,. \tag{264}$$

This is also the gravitational force between two (numerically corrected) Planck masses $\sqrt{\hbar c/8G}$ located at the cosmological distance $1/4\sqrt{\Lambda}$. If we make the somewhat wishful assumption that expression (264) is the smallest possible force in nature (the numerical factors are not yet verified), we get the fascinating conjecture that the full theory of general relativity, including the cosmological constant, may be defined by the combination of a *maximum* and a *minimum* force in nature. (Can you find a smaller force?)

Challenge 764 d

Proving the minimum force conjecture is more involved than for the case of the maxi-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

mum force. So far, only some hints are possible. Like the maximum force, the minimum force must be compatible with gravitation, must not be contradicted by any experiment, and must withstand any Gedanken experiment. A quick check shows that the minimum force, as we have just argued, allows us to deduce gravitation, is an invariant, and is not contradicted by any experiment. There are also hints that there may be no way to generate or measure a smaller value. For example, the minimum force corresponds to the energy per length contained by a photon with a wavelength of the size of the universe. It is hard – but maybe not impossible – to imagine the production of a still smaller force.

We have seen that the maximum force principle and general relativity fail to fix the value of the cosmological constant. Only a unified theory can do so. We thus get two requirements for such a theory. First, any unified theory must predict the same upper limit to force. Secondly, a unified theory must fix the cosmological constant. The appearance of $\hbar$ in the conjectured expression for the minimum force suggests that the minimum force is determined by a combination of general relativity and quantum theory. The proof of this suggestion and the direct measurement of the minimum force are two important challenges for our ascent beyond general relativity.

We are now ready to explore the consequences of general relativity and its field equations in more detail. We start by focusing on the concept of space-time curvature in everyday life, and in particular, on its consequences for the observation of motion.

Acknowledgement

Chapter 17

THE NEW IDEAS ON SPACE, TIME AND GRAVITY

> Sapere aude.*
>
> Horace *Epistulae*, 1, 2, 40.

Gravitational influences do transport energy.** Our description of motion must therefore be precise enough to imply that this transport can happen at most with the speed of light. Henri Poincaré stated this requirement as long ago as 1905. The results following from this principle will be fascinating: we will find that empty space can move, that the universe has a finite age and that objects can be in permanent free fall. It will turn out that empty space can be bent, although it is much stiffer than steel. Despite these strange consequences, the theory and all its predictions have been confirmed by all experiments.

The theory of universal gravitation, which describes motion due to gravity using the relation $a = GM/r^2$, allows speeds higher than that of light. Indeed, the speed of a mass in orbit is not limited. It is also unclear how the values of a and r depend on the observer. So this theory cannot be correct. In order to reach the correct description, called *general relativity* by Albert Einstein, we have to throw quite a few preconceptions overboard.

Ref. 392, Ref. 393

Rest and free fall

The opposite of motion in daily life is a body at rest, such as a child sleeping or a rock defying the waves. A body is at rest whenever it is not disturbed by other bodies. In the Galilean description of the world, rest is the *absence of velocity*. In special relativity, rest became *inertial motion*, since no inertially moving observer can distinguish its own motion from rest: nothing disturbs him. Both the rock in the waves and the rapid protons crossing the galaxy as cosmic rays are at rest. The inclusion of gravity leads us to an even more general definition.

Challenge 765 e

If any body moving inertially is to be considered at rest, then any body in free fall must also be. Nobody knows this better than Joseph Kittinger, the man who in August 1960 stepped out of a balloon capsule at the record height of 31.3 km. At that altitude, the air is so thin that during the first minute of his free fall he felt completely at rest, as if he were floating. Although an experienced parachutist, he was so surprised that he had to turn upwards in order to convince himself that he was indeed moving away from his balloon! Despite his lack of any sensation of movement, he was falling at up to 274 m/s or 988 km/h with respect to the Earth's surface. He only started feeling something when

Ref. 394

* 'Venture to be wise.' Horace is Quintus Horatius Flaccus, (65–8 BCE), the great Roman poet.

** The details of this statement are far from simple. They are discussed on page 525 and page 559.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

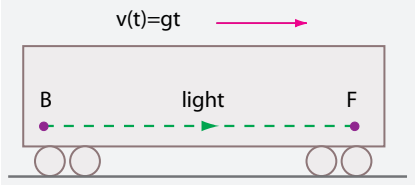

FIGURE 271 Inside an accelerating train or bus

he encountered the first substantial layers of air. That was when his free fall started to be disturbed. Later, after four and a half minutes of fall, his special parachute opened; and nine minutes later he landed in New Mexico.

Kittinger and all other observers in free fall, such as the cosmonauts circling the Earth or the passengers in parabolic aeroplane flights,* make the same observation: it is impossible to distinguish anything happening in free fall from what would happen at rest. This impossibility is called the *principle of equivalence*; it is one of the starting points of general relativity. It leads to the most precise – and final – definition of rest: *rest is free fall*. Rest is lack of disturbance; so is free fall.

The set of all free-falling observers at a point in space-time generalizes the special-relativistic notion of the set of the inertial observers at a point. This means that we must describe motion in such a way that not only inertial but also freely falling observers can talk to each other. In addition, a full description of motion must be able to describe gravitation and the motion it produces, and it must be able to describe motion for any observer imaginable. General relativity realizes this aim.

As a first step, we put the result in simple words: true *motion is the opposite of free fall*. This statement immediately rises a number of questions: Most trees or mountains are not
Challenge 766 s in free fall, thus they are not at rest. What motion are they undergoing? And if free fall is rest, what is weight? And what then is gravity anyway? Let us start with the last question.

What is gravity? – A second answer

In the beginning, we described gravity as the shadow of the maximum force. But there is a second way to describe it, more related to everyday life. As William Unruh likes to
Ref. 395 explain, the constancy of the speed of light for all observers implies a simple conclusion: *gravity is the uneven running of clocks at different places*.** Of course, this seemingly ab-
Challenge 768 e surd definition needs to be checked. The definition does not talk about a single situation seen by different observers, as we often did in special relativity. The definition depends of the fact that neighbouring, identical clocks, fixed against each other, run differently in the presence of a gravitational field when watched by the *same* observer; moreover, this difference is directly related to what we usually call gravity. There are two ways to check this connection: by experiment and by reasoning. Let us start with the latter method, as it is cheaper, faster and more fun.

* Nowadays it is possible to book such flights in specialized travel agents.

** Gravity is also the uneven length of metre bars at different places, as we will see below. Both effects are needed to describe it completely; but for daily life on Earth, the clock effect is sufficient, since it is much
Challenge 767 s larger than the length effect, which can usually be neglected. Can you see why?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

An observer feels no difference between gravity and constant acceleration. We can thus study constant acceleration and use a way of reasoning we have encountered already in the chapter on special relativity. We assume light is emitted at the back end of a train of length Δh that is accelerating forward with acceleration g, as shown in Figure 271. The light arrives at the front after a time $t = \Delta h/c$. However, during this time the accelerating train has picked up some additional velocity, namely $\Delta v = gt = g\Delta h/c$. As a result, because of the Doppler effect we encountered in our discussion of special relativity, the frequency f of the light arriving at the front has changed. Using the expression of the Doppler effect, we thus get*

Page 431

Challenge 769 e

$$\frac{\Delta f}{f} = \frac{g\Delta h}{c^2} \,. \tag{265}$$

The sign of the frequency change depends on whether the light motion and the train acceleration are in the same or in opposite directions. For actual trains or buses, the frequency change is quite small; nevertheless, it is measurable. Acceleration induces frequency changes in light. Let us compare this effect of acceleration with the effects of gravity.

Challenge 771 s

To measure time and space, we use light. What happens to light when gravity is involved? The simplest experiment is to let light fall or rise. In order to deduce what must happen, we add a few details. Imagine a conveyor belt carrying masses around two wheels, a low and a high one, as shown in Figure 272. The descending, grey masses are slightly larger. Whenever such a larger mass is near the bottom, some mechanism – not shown in the figure – converts the mass surplus to light, in accordance with the equation $E = mc^2$, and sends the light up towards the top.** At the top, one of the lighter, white masses passing by absorbs the light and, because of its added weight, turns the conveyor belt until it reaches the bottom. Then the process repeats.***

Ref. 396

As the grey masses on the descending side are always heavier, the belt would turn for ever and this system could continuously *generate* energy. However, since energy conservation is at the basis of our definition of time, as we saw in the beginning of our walk, the whole process must be impossible. We have to conclude that the light changes its energy when climbing. The only possibility is that the light arrives at the top with a frequency *different* from the one at which it is emitted from the bottom.****

Page 219

In short, it turns out that rising light is gravitationally red-shifted. Similarly, the light descending from the top of a tree down to an observer is *blue-shifted*; this gives a darker colour to the top in comparison with the bottom of the tree. General relativity thus says that trees have different shades of green along their height.***** How big is the effect? The result deduced from the drawing is again the one of formula (265). That is what we

Challenge 774 e

* The expression $v = gt$ is valid only for non-relativistic speeds; nevertheless, the conclusion of this section is not affected by this approximation.

Challenge 770 e

** As in special relativity, here and in the rest of our mountain ascent, the term 'mass' always refers to rest mass.

*** Can this process be performed with 100% efficiency?

Challenge 772 s

**** The precise relation between energy and frequency of light is described and explained in our discussion on quantum theory, on page 997. But we know already from classical electrodynamics that the energy of light depends on its intensity and on its frequency.

***** How does this argument change if you include the illumination by the Sun?

Challenge 773 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

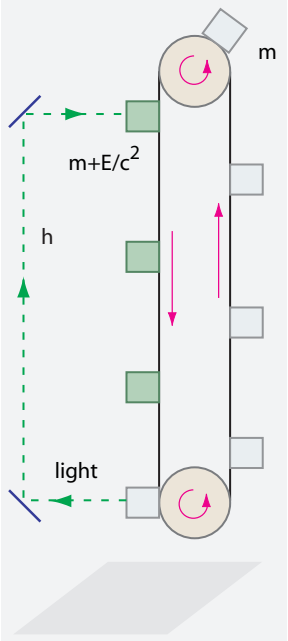

FIGURE 272 The necessity of blue- and red-shift of light: why trees are greener at the bottom

would, as light moving in an accelerating train and light moving in gravity are equivalent situations, as you might want to check yourself. The formula gives a relative change of frequency of only $1.1 \cdot 10^{-16}$ /m near the surface of the Earth. For trees, this so-called *gravitational red-shift* or *gravitational Doppler effect* is far too small to be observable, at least using normal light.

Challenge 775 s

Ref. 397

In 1911, Einstein proposed an experiment to check the change of frequency with height by measuring the red-shift of light emitted by the Sun, using the famous Fraunhofer lines as colour markers. The results of the first experiments, by Schwarzschild and others, were unclear or even negative, due to a number of other effects that induce colour changes at high temperatures. But in 1920 and 1921, Grebe and Bachem, and independently Perot, confirmed the gravitational red-shift with careful experiments. In later years, technological advances made the measurements much easier, until it was even possible to measure the effect on Earth. In 1960, in a classic experiment using the Mössbauer effect, Pound and Rebka confirmed the gravitational red-shift in their university tower using γ radiation.

Page 1041

Ref. 398

But our two thought experiments tell us much more. Let us use the same arguments as in the case of special relativity: a colour change implies that clocks run differently at different heights, just as they run differently in the front and in the back of a train. The time difference $\Delta\tau$ is predicted to depend on the height difference Δh and the acceleration of gravity g according to

$$\frac{\Delta\tau}{\tau} = \frac{\Delta f}{f} = \frac{g\Delta h}{c^2} \,. \tag{266}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Therefore, in gravity, *time is height-dependent*. That was exactly what we claimed above. In fact, *height makes old*. Can you confirm this conclusion? Challenge 776 ny

In 1972, by flying four precise clocks in an aeroplane while keeping an identical one on the ground, Hafele and Keating found that clocks indeed run differently at different altitudes according to expression (266). Subsequently, in 1976, the team of Vessot shot a precision clock based on a maser – a precise microwave generator and oscillator – upwards on a missile. The team compared the maser inside the missile with an identical maser on the ground and again confirmed the above expression. In 1977, Briatore and Leschiutta showed that a clock in Torino indeed ticks more slowly than one on the top of the Monte Rosa. They confirmed the prediction that on Earth, for every 100 m of height gained, people age more rapidly by about 1 ns per day. This effect has been confirmed for all systems for which experiments have been performed, such as several planets, the Sun and numerous other stars. Ref. 399 Ref. 400 Ref. 401 Challenge 777 ny

Do these experiments show that time changes or are they simply due to clocks that function badly? Take some time and try to settle this question. We will give one argument only: gravity does change the colour of light, and thus really does change time. Clock precision is not an issue here. Challenge 778 e

In summary, gravity is indeed the uneven running of clocks at different heights. Note that an observer at the lower position and another observer at the higher position *agree* on the result: both find that the upper clock goes faster. In other words, when gravity is present, space-time is *not* described by the Minkowski geometry of special relativity, but by some more general geometry. To put it mathematically, whenever gravity is present, the 4-distance ds^2 between events is different from the expression without gravity:

$$ds^2 \neq c^2dt^2 - dx^2 - dy^2 - dz^2 \,. \tag{267}$$

We will give the correct expression shortly.

Is this view of gravity as height-dependent time really reasonable? No. It turns out that it is not yet strange enough! Since the speed of light is the same for all observers, we can say more. If time changes with height, length must also do so! More precisely, if clocks run differently at different heights, the length of metre bars must also change with height. Can you confirm this for the case of horizontal bars at different heights? Challenge 779 ny

If length changes with height, the circumference of a circle around the Earth *cannot* be given by $2\pi r$. An analogous discrepancy is also found by an ant measuring the radius and circumference of a circle traced on the surface of a basketball. Indeed, gravity implies that humans are in a situation analogous to that of ants on a basketball, the only difference being that the circumstances are translated from two to three dimensions. We conclude that wherever gravity plays a role, space is *curved*.

What tides tell us about gravity

During his free fall, Kittinger was able to specify an inertial frame for himself. Indeed, he felt completely at rest. Does this mean that it is impossible to distinguish acceleration from gravitation? No: distinction *is* possible. We only have to compare *two* (or more) falling observers.

Kittinger could not have found a frame which is also inertial for a colleague falling

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

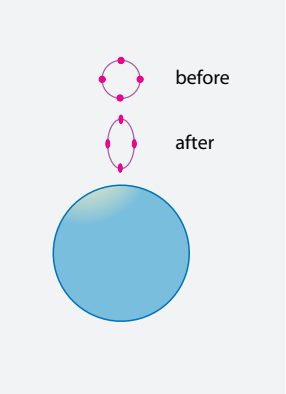

FIGURE 273 Tidal effects: the only effect bodies feel when falling

Challenge 780 e

on the opposite side of the Earth. Such a common frame does not exist. In general, it is impossible to find a *single* inertial reference frame describing different observers freely falling near a mass. In fact, it is impossible to find a common inertial frame even for *nearby* observers in a gravitational field. Two nearby observers observe that during their fall, their relative distance changes. (Why?) The same happens to orbiting observers.

Challenge 781 s

In a closed room in orbit around the Earth, a person or a mass at the centre of the room would not feel any force, and in particular no gravity. But if several particles are located in the room, they will behave differently depending on their exact positions in the room. Only if two particles were on exactly the same orbit would they keep the same relative position. If one particle is in a lower or higher orbit than the other, they will depart from each other over time. Even more interestingly, if a particle in orbit is displaced sideways, it will oscillate around the central position. (Can you confirm this?)

Challenge 782 ny

Gravitation leads to changes of relative distance. These changes evince another effect, shown in Figure 273: an extended body in free fall is slightly *squeezed*. This effect also tells us that it is an essential feature of gravity that free fall is *different* from point to point. That rings a bell. The squeezing of a body is the same effect as that which causes the tides. Indeed, the bulging oceans can be seen as the squeezed Earth in its fall towards the Moon. Using this result of universal gravity we can now affirm: the essence of gravity is the observation of tidal effects.

Page 158

Ref. 402

In other words, gravity is simple only *locally*. Only locally does it look like acceleration. Only locally does a falling observer like Kittinger feel at rest. In fact, only a point-like observer does so! As soon as we take spatial extension into account, we find tidal effects. *Gravity is the presence of tidal effects.* The absence of tidal effects implies the absence of gravity. Tidal effects are the everyday consequence of height-dependent time. Isn't this a beautiful conclusion?

In principle, Kittinger could have *felt* gravitation during his free fall, even with his eyes closed, had he paid attention to himself. Had he measured the distance change between his two hands, he would have found a tiny decrease which could have told him that he was falling. This tiny decrease would have forced Kittinger to a strange conclusion. Two inertially moving hands should move along two parallel lines, always keeping the same distance. Since the distance changes, he must conclude that in the space around him lines

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

starting out in parallel do not remain so. Kittinger would have concluded that the space around him was similar to the surface of the Earth, where two lines starting out north, parallel to each other, also change distance, until they meet at the North Pole. In other words, Kittinger would have concluded that he was in a *curved* space.

By studying the change in distance between his hands, Kittinger could even have concluded that the curvature of space changes with height. Physical space differs from a sphere, which has constant curvature. Physical space is more involved. The effect is extremely small, and cannot be felt by human senses. Kittinger had no chance to detect anything. Detection requires special high-sensitivity apparatus. However, the conclusion remains valid. Space-time is *not* described by Minkowski geometry when gravity is present. Tidal effects imply space-time curvature. Gravity is the curvature of space-time.

Bent space and mattresses

> Wenn ein Käfer über die Oberfläche einer Kugel krabbelt, merkt er wahrscheinlich nicht, daß der Weg, den er zurücklegt, gekrümmt ist. Ich dagegen hatte das Glück, es zu merken.*
>
> Albert Einstein's answer to his son Eduard's question about the reason for his fame

On the 7th of November 1919, Albert Einstein became world-famous. On that day, an article in the *Times* newspaper in London announced the results of a double expedition to South America under the heading 'Revolution in science / new theory of the universe / Newtonian ideas overthrown'. The expedition had shown unequivocally – though not for the first time – that the theory of universal gravity, essentially given by $a = GM/r^2$, was wrong, and that instead space was *curved*. A worldwide mania started. Einstein was presented as the greatest of all geniuses. 'Space warped' was the most common headline. Einstein's papers on general relativity were reprinted in full in popular magazines. People could read the field equations of general relativity, in tensor form and with Greek indices, in *Time* magazine. Nothing like this has happened to any other physicist before or since. What was the reason for this excitement?

The expedition to the southern hemisphere had performed an experiment proposed by Einstein himself. Apart from seeking to verify the change of time with height, Einstein had also thought about a number of experiments to detect the curvature of space. In the one that eventually made him famous, Einstein proposed to take a picture of the stars near the Sun, as is possible during a solar eclipse, and compare it with a picture of the same stars at night, when the Sun is far away. Einstein predicted a change in position of 1.75′ (1.75 seconds of arc) for star images at the border of the Sun, a value *twice* as large as that predicted by universal gravity. The prediction, corresponding to about 1/40 mm on the photographs, was confirmed in 1919, and thus universal gravity was ruled out.

Ref. 403

Page 161

Does this result *imply* that space is curved? Not by itself. In fact, other explanations could be given for the result of the eclipse experiment, such as a potential differing from the inverse square form. However, the eclipse results are not the only data. We already know about the change of time with height. Experiments show that two observers at

* 'When an insect walks over the surface of a sphere it probably does not notice that the path it walks is curved. I, on the other hand, had the luck to notice it.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

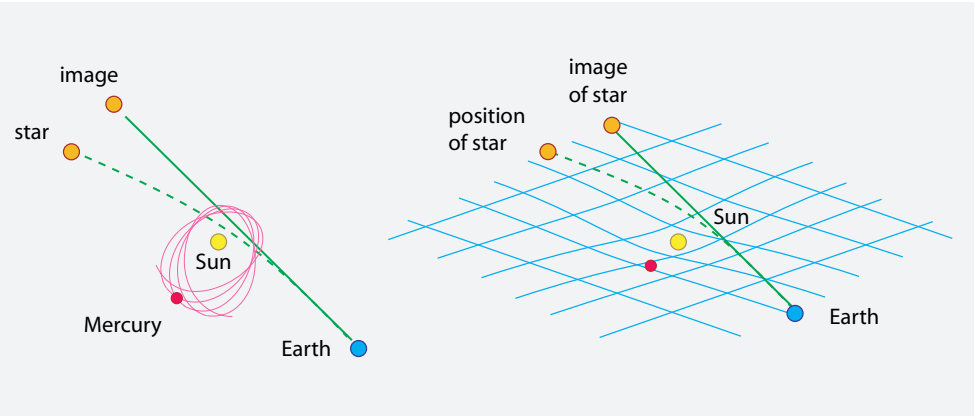

FIGURE 274 The mattress model of space: the path of a light beam and of a satellite near a spherical mass

different heights measure the same value for the speed of light c near themselves. But these experiments also show that if an observer measures the speed of light at the position of the *other* observer, he gets a value differing from c, since his clock runs differently. There is only one possible solution to this dilemma: metre bars, like clocks, also change with height, and in such a way as to yield the same speed of light everywhere.

Challenge 783 ny

If the speed of light is constant but clocks and metre bars change with height, the conclusion must be that *space is curved near masses*. Many physicists in the twentieth century checked whether metre bars really behave differently in places where gravity is present. And indeed, curvature has been detected around several planets, around all the hundreds of stars where it could be measured, and around dozens of galaxies. Many indirect effects of curvature around masses, to be described in detail below, have also been observed. All results confirm the curvature of space and space-time around masses, and in addition confirm the curvature values predicted by general relativity. In other words, metre bars near masses do indeed change their size from place to place, and even from orientation to orientation. Figure 274 gives an impression of the situation.

Ref. 404

Challenge 784 s

But beware: the right-hand figure, although found in many textbooks, can be misleading. It can easily be mistaken for a reproduction of a *potential* around a body. Indeed, it is impossible to draw a graph showing curvature and potential separately. (Why?) We will see that for small curvatures, it is even possible to explain the change in metre bar length using a potential only. Thus the figure does not really cheat, at least in the case of weak gravity. But for large and changing values of gravity, a potential cannot be defined, and thus there is indeed no way to avoid using curved space to describe gravity. In summary, if we imagine space as a sort of generalized mattress in which masses produce deformations, we have a reasonable model of space-time. As masses move, the deformation follows them.

The acceleration of a test particle only depends on the curvature of the mattress. It does not depend on the mass of the test particle. So the mattress model explains why all bodies fall in the same way. (In the old days, this was also called the equality of the inertial and gravitational mass.)

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Space thus behaves like a frictionless mattress that pervades everything. We live inside the mattress, but we do not feel it in everyday life. Massive objects pull the foam of the mattress towards them, thus deforming the shape of the mattress. More force, more energy or more mass imply a larger deformation. (Does the mattress remind you of the aether? Do not worry: physics eliminated the concept of aether because it is indistinguishable from vacuum.)

Page 757

If gravity means curved space, then any accelerated observer, such as a man in a departing car, must also observe that space is curved. However, in everyday life we do not notice any such effect, because for accelerations and sizes of of everyday life the curvature values are too small to be noticed. Could you devise a sensitive experiment to check the prediction?

Challenge 785 ny

Curved space-time

Figure 274 shows the curvature of space only, but in fact space-time is curved. We will shortly find out how to describe both the shape of space and the shape of space-time, and how to measure their curvature.

Let us have a first attempt to describe nature with the idea of curved space-time. In the case of Figure 274, the best description of events is with the use of the time t shown by a clock located at spatial infinity; that avoids problems with the uneven running of clocks at different distances from the central mass. For the radial coordinate r, the most practical choice to avoid problems with the curvature of space is to use the circumference of a circle around the central body, divided by 2π. The curved shape of space-time is best described by the behaviour of the space-time distance $\mathrm{d}s$, or by the wristwatch time $\mathrm{d}\tau = \mathrm{d}s/c$, between two neighbouring points with coordinates (t, r) and $(t + \mathrm{d}t, r + \mathrm{d}r)$.

Page 422

As we saw above, gravity means that in spherical coordinates we have

Page 502

$$\mathrm{d}\tau^2 = \frac{\mathrm{d}s^2}{c^2} \neq \mathrm{d}t^2 - \mathrm{d}r^2/c^2 - r^2\mathrm{d}\varphi^2/c^2 \,. \tag{268}$$

The inequality expresses the fact that space-time is *curved*. Indeed, the experiments on time change with height confirm that the space-time interval around a spherical mass is given by

$$\mathrm{d}\tau^2 = \frac{\mathrm{d}s^2}{c^2} = \left(1 - \frac{2GM}{rc^2}\right)\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{c^2 - \frac{2GM}{r}} - \frac{r^2}{c^2}\mathrm{d}\varphi^2 \,. \tag{269}$$

This expression is called the *Schwarzschild metric* after one of its discoverers.* The metric (269) describes the curved shape of space-time around a spherical non-rotating mass. It is well approximated by the Earth or the Sun. (Why can their rotation be neglected?) Expression (269) also shows that gravity's strength around a body of mass M and radius

Challenge 786 s

* Karl Schwarzschild (1873–1916), important German astronomer; he was one of the first people to understand general relativity. He published his formula in December 1915, only a few months after Einstein had published his field equations. He died prematurely, at the age of 42, much to Einstein's distress. We will deduce the form of the metric later on, directly from the field equations of general relativity. The other discoverer of the metric, unknown to Einstein, was the Dutch physicist J. Droste.

Ref. 405

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

R is measured by a dimensionless number h defined as

$$h = \frac{2G}{c^2}\frac{M}{R} \,. \tag{270}$$

This ratio expresses the gravitational strain with which lengths and the vacuum are deformed from the flat situation of special relativity, and thus also determines how much clocks slow down when gravity is present. (The ratio also reveals how far one is from any possible horizon.) On the surface of the Earth the ratio h has the small value of $1.4 \cdot 10^{-9}$; on the surface of the Sun is has the somewhat larger value of $4.2 \cdot 10^{-6}$. The precision of modern clocks allows one to detect such small effects quite easily. The various consequences and uses of the deformation of space-time will be discussed shortly.

We note that if a mass is highly concentrated, in particular when its radius becomes *equal* to its so-called *Schwarzschild radius*

$$R_S = \frac{2GM}{c^2} \,, \tag{271}$$

the Schwarzschild metric behaves strangely: at that location, *time disappears* (note that t is time at infinity). At the Schwarzschild radius, the wristwatch time (as shown by a clock at infinity) stops – and a horizon appears. What happens precisely will be explored below. This situation is not common: the Schwarzschild radius for a mass like the Earth is 8.8 mm, and for the Sun is 3.0 km; you might want to check that the object size for every system in everyday life is larger than its Schwarzschild radius. Bodies which reach this limit are called *black holes*; we will study them in detail shortly. In fact, general relativity states that *no* system in nature is smaller than its Schwarzschild size, in other words that the ratio h defined by expression (270) is never above unity.

Page 606
Challenge 787 e
Ref. 406

In summary, the results mentioned so far make it clear that *mass generates curvature*. The mass–energy equivalence we know from special relativity then tells us that as a consequence, space should also be curved by the presence of any type of energy–momentum. Every type of energy curves space-time. For example, light should also curve space-time. However, even the highest-energy beams we can create correspond to extremely small masses, and thus to unmeasurably small curvatures. Even heat curves space-time; but in most systems, heat is only about a fraction of 10^{-12} of total mass; its curvature effect is thus unmeasurable and negligible. Nevertheless it is still possible to show experimentally that energy curves space. In almost all atoms a sizeable fraction of the mass is due to the electrostatic energy among the positively charged protons. In 1968 Kreuzer confirmed that energy curves space with a clever experiment using a floating mass.

Ref. 407

It is straightforward to imagine that the uneven running of clock is the temporal equivalent of spatial curvature. Taking the two together, we conclude that when gravity is present, *space-time* is curved.

Challenge 788 ny

Let us sum up our chain of thoughts. Energy is equivalent to mass; mass produces gravity; gravity is equivalent to acceleration; acceleration is position-dependent time. Since light speed is constant, we deduce that *energy–momentum tells space-time to curve.* This statement is the first half of general relativity.

We will soon find out how to measure curvature, how to calculate it from energy–

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

momentum and what is found when measurement and calculation are compared. We will also find out that different observers measure different curvature values. The set of transformations relating one viewpoint to another in general relativity, the *diffeomorphism symmetry*, will tell us how to relate the measurements of different observers.

Since matter moves, we can say even more. Not only is space-time curved near masses, it also bends back when a mass has passed by. In other words, general relativity states that space, as well as space-time, is *elastic*. However, it is rather stiff: quite a lot stiffer than steel. To curve a piece of space by 1 % requires an energy density enormously larger than to curve a simple train rail by 1 %. This and other interesting consequences of the elasticity of space-time will occupy us for a while.

Ref. 408

Challenge 789 ny

The speed of light and the gravitational constant

> “Si morior, moror.*”

We continue on the way towards precision in our understanding of gravitation. All our theoretical and empirical knowledge about gravity can be summed up in just two general statements. The first principle states:

▷ *The speed v of a physical system is bounded above:*

$$v \leqslant c \tag{272}$$

for all observers, where c is the speed of light.

The theory following from this first principle, *special* relativity, is extended to *general* relativity by adding a second principle, characterizing gravitation. There are several equivalent ways to state this principle. Here is one.

▷ *For all observers, the force F on a system is limited by*

$$F \leqslant \frac{c^4}{4G} \,, \tag{273}$$

where G is the universal constant of gravitation.

In short, there is a maximum force in nature. Gravitation leads to attraction of masses. However, this force of attraction is limited. An equivalent statement is:

Challenge 790 e

▷ *For all observers, the size L of a system of mass M is limited by*

$$\frac{L}{M} \geqslant \frac{4G}{c^2} \,. \tag{274}$$

* ‘If I rest, I die.’ This is the motto of the bird of paradise.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In other words, a massive system cannot be more concentrated than a non-rotating black hole of the same mass. Another way to express the principle of gravitation is the following:

▷ *For all systems, the emitted power P is limited by*

$$P \leqslant \frac{c^5}{4G} \,. \tag{275}$$

In short, there is a maximum power in nature.

The three limits given above are all equivalent to each other; and no exception is known or indeed possible. The limits include universal gravity in the non-relativistic case. They tell us *what* gravity is, namely curvature, and *how* exactly it behaves. The limits allow us to determine the curvature in all situations, at all space-time events. As we have seen above, the speed limit together with any one of the last three principles imply all of general relativity.*

Page 476

For example, can you show that the formula describing gravitational red-shift complies with the general limit (274) on length-to-mass ratios?

Challenge 791 ny

We note that any formula that contains the speed of light c is based on special relativity, and if it contains the constant of gravitation G, it relates to universal gravity. If a formula contains *both* c and G, it is a statement of general relativity. The present chapter frequently underlines this connection.

Our mountain ascent so far has taught us that a precise description of motion requires the specification of all allowed viewpoints, their characteristics, their differences, and the transformations between them. From now on, *all* viewpoints are allowed, without exception: anybody must be able to talk to anybody else. It makes no difference whether an observer feels gravity, is in free fall, is accelerated or is in inertial motion. Furthermore, people who exchange left and right, people who exchange up and down or people who say that the Sun turns around the Earth must be able to talk to each other and to us. This gives a much larger set of viewpoint transformations than in the case of special relativity; it makes general relativity both difficult and fascinating. And since all viewpoints are allowed, the resulting description of motion is *complete*.**

Why does a stone thrown into the air fall back to Earth? – Geodesics

> A genius is somebody who makes all possible mistakes in the shortest possible time.
>
> Anonymous

In our discussion of special relativity, we saw that inertial or free-floating motion is the motion which connecting two events that requires the *longest* proper time. In the absence of gravity, the motion fulfilling this requirement is *straight* (rectilinear) motion. On the other hand, we are also used to thinking of light rays as being straight. Indeed, we are all

Page 455

Page 61

* This didactic approach is unconventional. It is possible that is has been pioneered by the present author. The British physicist Gary Gibbons also developed similar ideas independently.

Ref. 378

** Or it would be, were it not for a small deviation called quantum theory.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

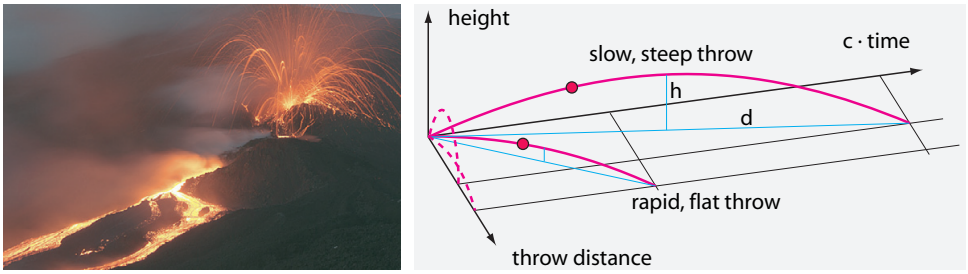

FIGURE 275 All paths of flying stones, independently of their speed and angle, have the same curvature in space-time (photograph © Marco Fulle)

accustomed to check the straightness of an edge by looking along it. Whenever we draw the axes of a physical coordinate system, we imagine either drawing paths of light rays or drawing the motion of freely moving bodies.

In the absence of gravity, object paths and light paths coincide. However, in the presence of gravity, objects do not move along light paths, as every thrown stone shows. Light does not define spatial straightness any more. In the presence of gravity, both light and matter paths are bent, though by *different* amounts. But the original statement remains valid: even when gravity is present, bodies follow paths of longest possible proper time. For matter, such paths are called *timelike geodesics*. For light, such paths are called *lightlike* or *null geodesics*.

We note that in space-time, geodesics are the curves with *maximal* length. This is in contrast with the case of pure space, such as the surface of a sphere, where geodesics are the curves of *minimal* length. In simple words, *stones fall because they follow geodesics*. Let us perform a few checks of this statement.

Since stones move by maximizing proper time for inertial observers, they also must do so for freely falling observers, like Kittinger. In fact, they must do so for all observers. The equivalence of falling paths and geodesics is at least coherent.

If falling is seen as a consequence of the Earth's surface approaching – as we will argue later on – we can deduce directly that falling implies a proper time that is as long as possible. Free fall indeed is motion along geodesics.

Challenge 792 ny

We saw above that gravitation follows from the existence of a maximum force. The result can be visualized in another way. If the gravitational attraction between a central body and a satellite were *stronger* than it is, black holes would be smaller than they are; in that case the maximum force limit and the maximum speed could be exceeded by getting close to such a black hole. If, on the other hand, gravitation were *weaker* than it is, there would be observers for which the two bodies would not interact, thus for which they would not form a physical system. In summary, a maximum force of $c^4/4G$ implies universal gravity. There is no difference between stating that all bodies attract through gravitation and stating that there is a maximum force with the value $c^4/4G$. But at the same time, the maximum force principle implies that objects move on geodesics. Can you show this?

Challenge 793 ny

Let us turn to an experimental check. If falling is a consequence of curvature, then the paths of *all* stones thrown or falling near the Earth must have the *same* curvature in space-time. Take a stone thrown horizontally, a stone thrown vertically, a stone thrown

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

rapidly, or a stone thrown slowly: it takes only two lines of argument to show that *in space-time* all their paths are approximated to high precision by circle segments, as shown in Figure 275. All paths have the *same* curvature radius r, given by

Challenge 794 ny

$$r = \frac{c^2}{g} \approx 9.2 \cdot 10^{15}\,\mathrm{m}\,. \tag{276}$$

The large value of the radius, corresponding to a low curvature, explains why we do not notice it in everyday life. The parabolic shape typical of the path of a stone in everyday life is just the projection of the more fundamental path in 4-dimensional space-time into 3-dimensional space. The important point is that the value of the curvature does *not* depend on the details of the throw. In fact, this simple result could have suggested the ideas of general relativity to people a full century before Einstein; what was missing was the recognition of the importance of the speed of light as limit speed. In any case, this simple calculation confirms that falling and curvature are connected. As expected, and as mentioned already above, the curvature diminishes at larger heights, until it vanishes at infinite distance from the Earth. Now, given that the curvature of all paths for free fall is the same, and given that all such paths are paths of least action, it is straightforward that they are also geodesics.

If we describe fall as a consequence of the curvature of space-time, we must show that the description with geodesics reproduces all its features. In particular, we must be able to explain that stones thrown with small speed fall back, and stones thrown with high speed escape. Can you deduce this from space curvature?

Challenge 795 ny

In summary, the motion of any particle falling freely 'in a gravitational field' is described by the same variational principle as the motion of a free particle in special relativity: the path maximizes the proper time $\int \mathrm{d}\tau$. We rephrase this by saying that any particle in free fall from point A to point B minimizes the action S given by

$$S = -mc^2 \int_A^B \mathrm{d}\tau\,. \tag{277}$$

That is all we need to know about the free fall of objects. As a consequence, any *deviation from free fall keeps you young*. The larger the deviation, the younger you stay.

As we will see below, the minimum action description of free fall has been tested extremely precisely, and no difference from experiment has ever been observed. We will also find out that for free fall, the predictions of general relativity and of universal gravity differ substantially both for particles near the speed of light and for central bodies of high density. So far, all experiments have shown that whenever the two predictions differ, general relativity is right, and universal gravity and other alternative descriptions are wrong.

Page 627
Ref. 409

All bodies fall along geodesics. This tells us something important. The fall of bodies does not depend on their mass. The geodesics are like 'rails' in space-time that tell bodies how to fall. In other words, space-time can indeed be imagined as a single, giant, deformed entity. Space-time is not 'nothing'; it is an entity of our thinking. The shape of this entity tells objects how to move. Space-time is thus indeed like an intangible mattress; this deformed mattress guides falling objects along its networks of geodesics.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Moreover, *bound* energy falls in the same way as mass, as is proven by comparing the fall of objects made of different materials. They have different percentages of bound energy. (Why?) For example, on the Moon, where there is no air, cosmonauts dropped steel balls and feathers and found that they fell together, alongside each other. The independence on material composition has been checked and confirmed over and over again.

Challenge 796 s

Ref. 410

Can light fall?

How does radiation fall? Light, like any radiation, is energy without rest mass. It moves like a stream of extremely fast and light objects. Therefore deviations from universal gravity become most apparent for light. How does light fall? Light cannot change speed. When light falls vertically, it only changes colour, as we have seen above. But light can also change direction. Long before the ideas of relativity became current, in 1801, the Prussian astronomer Johann Soldner understood that universal gravity implies that light is *deflected* when passing near a mass. He also calculated how the deflection angle depends on the mass of the body and the distance of passage. However, nobody in the nineteenth century was able to check the result experimentally.

Page 499

Ref. 411

Page 161

Obviously, light has energy, and energy has weight; the deflection of light by itself is thus *not* a proof of the curvature of space. General relativity also predicts a deflection angle for light passing masses, but of *twice* the classical Soldner value, because the curvature of space around large masses adds to the effect of universal gravity. The deflection of light thus only confirms the curvature of space if the *value* agrees with the one predicted by general relativity. This is the case: observations do coincide with predictions. More details will be given shortly.

Page 533

Mass is thus not necessary to feel gravity; energy is sufficient. This result of the mass–energy equivalence must become second nature when studying general relativity. In particular, light is not light-weight, but heavy. Can you argue that the curvature of light near the Earth must be the same as that of stones, given by expression (276)?

Challenge 797 ny

In summary, all experiments show that not only mass, but also energy falls along geodesics, whatever its type (bound or free), and whatever the interaction (be it electromagnetic or nuclear). Moreover, the motion of radiation confirms that space-time is curved.

Since experiments show that all particles fall in the same way, independently of their mass, charge or any other property, we can conclude that the system of all possible trajectories forms an independent structure. This structure is what we call *space-time*.

We thus find that *space-time tells matter, energy and radiation how to fall.* This statement is the second half of general relativity. It complements the first half, which states that energy tells space-time how to curve. To complete the description of macroscopic motion, we only need to add numbers to these statements, so that they become testable. As usual, we can proceed in two ways: we can deduce the equations of motion directly, or we can first deduce the Lagrangian and then deduce the equations of motion from it. But before we do that, let's have some fun.

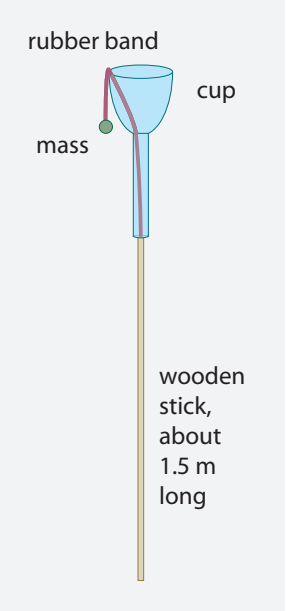

FIGURE 276 A puzzle: what is the simplest way to get the ball attached to the rubber band into the cup?

Curiosities and fun challenges about gravitation

> Wenn Sie die Antwort nicht gar zu ernst nehmen und sie nur als eine Art Spaß ansehen, so kann ich Ihnen das so erklären: Früher hat man geglaubt, wenn alle Dinge aus der Welt verschwinden, so bleiben noch Raum und Zeit übrig. Nach der Relativitätstheorie verschwinden aber auch Zeit und Raum mit den Dingen.*
>
> Albert Einstein in 1921 in New York

Take a plastic bottle and make some holes in it near the bottom. Fill the bottle with water, closing the holes with your fingers. If you let the bottle go, no water will leave the bottle during the fall. Can you explain how this experiment confirms the equivalence of rest and free fall? Challenge 798 s

* *

On his seventy-sixth birthday, Einstein received a birthday present specially made for him, shown in Figure 276. A rather deep cup is mounted on the top of a broom stick. The cup contains a weak piece of elastic rubber attached to its bottom, to which a ball is attached at the other end. In the starting position, the ball hangs outside the cup. The rubber is too weak to pull the ball into the cup against gravity. What is the most elegant

* 'If you do not take the answer too seriously and regard it only for amusement, I can explain it to you in the following way: in the past it was thought that if all things were to disappear from the world, space and time would remain. But following relativity theory, space and time would disappear together with the things.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 799 s way to get the ball into the cup?

* *

Gravity has the same properties in the whole universe – except in the US patent office. In 2005, it awarded a patent, Nr. 6 960 975, for an antigravity device that works by distorting space-time in such a way that gravity is 'compensated' (see patft.uspto.gov). Do you know
Challenge 800 s a simpler device?

* *

The radius of curvature of space-time at the Earth's surface is $9.2 \cdot 10^{15}$ m. Can you con-
Challenge 801 e firm this value?

* *

Challenge 802 ny A piece of wood floats on water. Does it stick out more or less in a lift accelerating upwards?

* *

Page 431 We saw in special relativity that if two twins are identically accelerated in the same direction, with one twin some distance ahead of the other, then the twin ahead ages more than the twin behind. Does this happen in a gravitational field as well? And what happens
Challenge 803 ny when the field varies with height, as on Earth?

* *

A maximum force and a maximum power also imply a maximum flow of mass. Can you
Challenge 804 ny show that no mass flow can exceed $1.1 \cdot 10^{35}$ kg/s?

* *

The experiments of Figure 271 and 272 differ in one point: one happens in flat space, the other in curved space. One seems to be connected with energy conservation, the other
Challenge 805 ny not. Do these differences invalidate the equivalence of the observations?

* *

Challenge 806 s How can cosmonauts weigh themselves to check whether they are eating enough?

* *

Is a cosmonaut in orbit really floating freely? No. It turns out that space stations and satellites are accelerated by several small effects. The important ones are the pressure of the light from the Sun, the friction of the thin air, and the effects of solar wind. (Micrometeorites can usually be neglected.) These three effects all lead to accelerations of the order of 10^{-6} m/s^2 to 10^{-8} m/s^2, depending on the height of the orbit. Can you estimate how long it would take an apple floating in space to hit the wall of a space station, starting
Challenge 807 s from the middle? By the way, what is the magnitude of the tidal accelerations in this situation?

* *

Page 95 There is no negative mass in nature, as discussed in the beginning of our walk (even

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

antimatter has *positive* mass). This means that gravitation cannot be shielded, in contrast to electromagnetic interactions. Since gravitation cannot be shielded, there is no way to make a perfectly isolated system. But such systems form the basis of thermodynamics! Page 1204 We will study the fascinating implications of this later on: for example, we will discover an *upper limit* for the entropy of physical systems.

* *

Can curved space be used to travel faster than light? Imagine a space-time in which two points could be connected either by a path leading through a flat portion, or by a second path leading through a partially curved portion. Could that curved portion be used to travel between the points faster than through the flat one? Mathematically, this is possible; however, such a curved space would need to have a *negative* energy density. Such a situation is incompatible with the definition of energy and with the non-existence Ref. 412 of negative mass. The statement that this does not happen in nature is also called the *weak* Challenge 808 ny *energy condition*. Is it implied by the limit on length-to-mass ratios?

* *

The statement of a length-to-mass limit $L/M \geqslant 4G/c^2$ invites experiments to try to overcome it. Can you explain what happens when an observer moves so rapidly past a mass Challenge 809 ny that the body's length contraction reaches the limit?

* *

There is an important mathematical property of $\mathbb{R}^3$ which singles out three dimensional space from all other possibilities. A closed (one-dimensional) curve can form knots *only* in $\mathbb{R}^3$: in any higher dimension it can always be unknotted. (The existence of knots also explains why three is the smallest dimension that allows chaotic particle motion.) However, general relativity does not say *why* space-time has three plus one dimensions. It is simply based on the fact. This deep and difficult question will be settled only in the last part of our mountain ascent.

* *

Henri Poincaré, who died in 1912, shortly before the general theory of relativity was finished, thought for a while that curved space was not a necessity, but only a possibility. He imagined that one could continue using Euclidean space provided light was permitted Challenge 810 ny to follow curved paths. Can you explain why such a theory is impossible?

* *

Can two hydrogen atoms circle each other, in their mutual gravitational field? What Challenge 811 s would the size of this 'molecule' be?

* *

Challenge 812 s Can two light pulses circle each other, in their mutual gravitational field?

* *

The various motions of the Earth mentioned in the section on Galilean physics, such as Page 132 its rotation around its axis or around the Sun, lead to various types of time in physics

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

and astronomy. The time defined by the best atomic clocks is called *terrestrial dynamical time*. By inserting leap seconds every now and then to compensate for the bad definition of the second (an Earth rotation does not take 86 400, but 86 400.002 seconds) and, in minor ways, for the slowing of Earth's rotation, one gets the *universal time coordinate* or UTC. Then there is the time derived from this one by taking into account all leap seconds. One then has the – different – time which would be shown by a non-rotating clock in the centre of the Earth. Finally, there is *barycentric dynamical time*, which is the time that would be shown by a clock in the centre of mass of the solar system. Only using this latter time can satellites be reliably steered through the solar system. In summary, relativity says goodbye to Greenwich Mean Time, as does British law, in one of the rare cases were the law follows science. (Only the BBC continues to use it.)

Page 917
Ref. 413

* *

Space agencies thus *have* to use general relativity if they want to get artificial satellites to Mars, Venus, or comets. Without its use, orbits would not be calculated correctly, and satellites would miss their targets and usually even the whole planet. In fact, space agencies play on the safe side: they use a generalization of general relativity, namely the so-called *parametrized post-Newtonian formalism*, which includes a continuous check on whether general relativity is correct. Within measurement errors, no deviation has been found so far.*

* *

General relativity is also used by space agencies around the world to calculate the exact positions of satellites and to tune radios to the frequency of radio emitters on them. In addition, general relativity is essential for the so-called *global positioning system*, or GPS. This modern navigation tool** consists of 24 satellites equipped with clocks that fly around the world. Why does the system need general relativity to operate? Since all the satellites, as well as any person on the surface of the Earth, travel in circles, we have $\mathrm{d}r = 0$, and we can rewrite the Schwarzschild metric (269) as

Ref. 414

$$\left(\frac{\mathrm{d}\tau}{\mathrm{d}t}\right)^2 = 1 - \frac{2GM}{rc^2} - \frac{r^2}{c^2}\left(\frac{\mathrm{d}\varphi}{\mathrm{d}t}\right)^2 = 1 - \frac{2GM}{rc^2} - \frac{v^2}{c^2}\,. \tag{279}$$

* To give an idea of what this means, the *unparametrized* post-Newtonian formalism, based on general relativity, writes the equation of motion of a body of mass m near a large mass M as a deviation from the inverse square expression for the acceleration a:

$$a = \frac{GM}{r^2} + f_2\frac{GM}{r^2}\frac{v^2}{c^2} + f_4\frac{GM}{r^2}\frac{v^4}{c^4} + f_5\frac{Gm}{r^2}\frac{v^5}{c^5} + \cdots \tag{278}$$

Here the numerical factors f_n are calculated from general relativity and are of order one. The first two odd terms are missing because of the (approximate) reversibility of general relativistic motion: gravity wave emission, which is irreversible, accounts for the small term f_5; note that it contains the small mass m instead of the large mass M. All factors f_n up to f_7 have now been calculated. However, in the solar system, only the term f_2 has ever been detected. This situation might change with future high-precision satellite experiments. Higher-order effects, up to f_5, have been measured in the binary pulsars, as discussed below.

Page 531

In a *parametrized* post-Newtonian formalism, all factors f_n, including the uneven ones, are fitted through the data coming in; so far all these fits agree with the values predicted by general relativity.

** For more information, see the www.gpsworld.com website.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 813 e For the relation between satellite time and Earth time we then get

$$\left(\frac{\mathrm{d}t_{\mathrm{sat}}}{\mathrm{d}t_{\mathrm{Earth}}}\right)^2 = \frac{1-\frac{2GM}{r_{\mathrm{sat}}c^2}-\frac{v_{\mathrm{sat}}^2}{c^2}}{1-\frac{2GM}{r_{\mathrm{Earth}}c^2}-\frac{v_{\mathrm{Earth}}^2}{c^2}} \,. \tag{280}$$

Challenge 814 s Ref. 415 Can you deduce how many microseconds a satellite clock gains every day, given that the GPS satellites orbit the Earth once every twelve hours? Since only three microseconds would give a position error of one kilometre after a single day, the clocks in the satellites must be adjusted to run slow by the calculated amount. The necessary adjustments are monitored, and so far have confirmed general relativity every single day, within experimental errors, since the system began operation.

* *

General relativity is the base of the sport of *geocaching*, the world-wide treasure hunt with help of GPS receivers. See the www.terracaching.com and www.geocaching.com websites for more details.

* *

Ref. 416 Challenge 815 d The gravitational constant G does not seem to change with time. The latest experiments limit its rate of change to less than 1 part in 10^{12} per year. Can you imagine how this can be checked?

Challenge 820 ny
Page 614

What percentage of the surface of the Sun can an observer at infinity see? We will examine this issue in more detail shortly.

What is weight?

There is no way for a *single* (and point-like) observer to distinguish the effects of gravity from those of acceleration. This property of nature allows one to make a strange statement: things *fall* because the surface of the Earth accelerates towards them. Therefore, the *weight* of an object results from the surface of the Earth accelerating upwards and pushing against the object. That is the principle of equivalence applied to everyday life. For the same reason, objects in free fall have no weight.

Let us check the numbers. Obviously, an accelerating surface of the Earth produces a weight for each body resting on it. This weight is proportional to the inertial mass. In other words, the inertial mass of a body is identical to the gravitational mass. This is indeed observed in experiments, and to the highest precision achievable. Roland von Eötvös* performed many such high-precision experiments throughout his life, without finding any discrepancy. In these experiments, he used the fact that the inertial mass determines centrifugal effects and the gravitational mass determines free fall. (Can you imagine how he tested the equality?) Recent experiments showed that the two masses agree to one part in 10^{-12}.

Ref. 419
Challenge 821 ny
Ref. 419

However, the mass equality is not a surprise. Remembering the definition of mass ratio as negative inverse acceleration ratio, independently of the origin of the acceleration, we are reminded that mass measurements cannot be used to distinguish between inertial and gravitational mass. As we have seen, the two masses are equal by definition in Galilean physics, and the whole discussion is a red herring. Weight is an intrinsic effect of mass.

Page 92
Page 163

The equality of acceleration and gravity allows us to imagine the following. Imagine stepping into a lift in order to move down a few stories. You push the button. The lift is pushed upwards by the accelerating surface of the Earth somewhat less than is the building; the building overtakes the lift, which therefore remains behind. Moreover, because of the weaker push, at the beginning everybody inside the lift feels a bit lighter. When the contact with the building is restored, the lift is accelerated to catch up with the accelerating surface of the Earth. Therefore we all feel as if we were in a strongly accelerating car, pushed in the direction opposite to the acceleration: for a short while, we feel heavier, until the lift arrives at its destination.

Why do apples fall?

> “Vires acquirit eundo.”
>
> Vergilius**

* Roland von Eötvös (b. 1848 Budapest, d. 1919 Budapest), Hungarian physicist. He performed many high-precision gravity experiments; among other discoveries, he discovered the effect named after him. The university of Budapest is named after him.

** ‘Going it acquires strength.’ Publius Vergilius Maro (b. 70 BCE Andes, d. 19 BCE Brundisium), from the *Aeneid* 4, 175.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

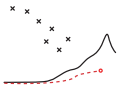
An accelerating car will soon catch up with an object thrown forward from it. For the same reason, the surface of the Earth soon catches up with a stone thrown upwards, because it is continually accelerating upwards. If you enjoy this way of seeing things, imagine an apple falling from a tree. At the moment when it detaches, it stops being accelerated upwards by the branch. The apple can now enjoy the calmness of real rest. Because of our limited human perception, we call this state of rest free fall. Unfortunately, the accelerating surface of the Earth approaches mercilessly and, depending on the time for which the apple stayed at rest, the Earth hits it with a greater or lesser velocity, leading to more or less severe shape deformation.

Falling apples also teach us not to be disturbed any more by the statement that gravity is the uneven running of clocks with height. In fact, this statement is *equivalent* to saying that the surface of the Earth is accelerating upwards, as the discussion above shows.

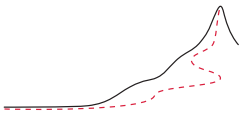
Challenge 822 ny

Can this reasoning be continued indefinitely? We can go on for quite a while. It is fun to show how the Earth can be of constant radius even though its surface is accelerating upwards everywhere. We can thus play with the equivalence of acceleration and gravity. However, this equivalence is only useful in situations involving only one accelerating body. The equivalence between acceleration and gravity ends as soon as *two* falling objects are studied. Any study of several bodies inevitably leads to the conclusion that gravity is not acceleration; *gravity is curved space-time*.

Many aspects of gravity and curvature can be understood with no or only a little mathematics. The next section will highlight some of the differences between universal gravity and general relativity, showing that only the latter description agrees with experiment. After that, a few concepts relating to the measurement of curvature are introduced and applied to the motion of objects and space-time. If the reasoning gets too involved for a first reading, skip ahead. In any case, the section on the stars, cosmology and black holes again uses little mathematics.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 18

MOTION IN GENERAL RELATIVITY – BENT LIGHT AND WOBBLING VACUUM

> Einstein explained his theory to me every day, and on my arrival I was fully convinced that the understood it.
>
> Chaim Weizmann, first president of Israel.

Ref. 420

Before we tackle the details of general relativity, we will explore how the motion of objects and light *differs* from that predicted by universal gravity, and how these differences can be measured.

WEAK FIELDS

Gravity is strong near horizons. This happens when the mass M and the distance scale R obey

$$\frac{2GM}{Rc^2} \approx 1\,. \tag{282}$$

Therefore, gravity is strong mainly in three situations: near black holes, near the horizon of the universe, and at extremely high particle energies. The first two cases are explored later on, while the last will be explored in the final part of our mountain ascent. In contrast, in most regions of the universe there are *no* nearby horizons; in these cases, gravity is a *weak* effect. Despite the violence of avalanches or of falling asteroids, in everyday life gravity is much weaker than the maximum force. On the Earth the ratio just mentioned is only about 10^{-9}. In this and all cases of everyday life, gravitation can still be approximated by a field, despite what was said above. These weak field situations are interesting because they are simple to understand; they mainly require for their explanation the different running of clocks at different heights. Weak field situations allow us to mention space-time curvature only in passing, and allow us to continue to think of gravity as a source of acceleration. However, the change of time with height already induces many new and interesting effects. The only thing we need is a consistent relativistic treatment.

The Thirring effects

In 1918, the Austrian physicist Hans Thirring published two simple and beautiful predictions of motions, one of them with his collaborator Josef Lense. Neither motion appears in universal gravity, but they both appear in general relativity. Figure 277 shows these

Ref. 421

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

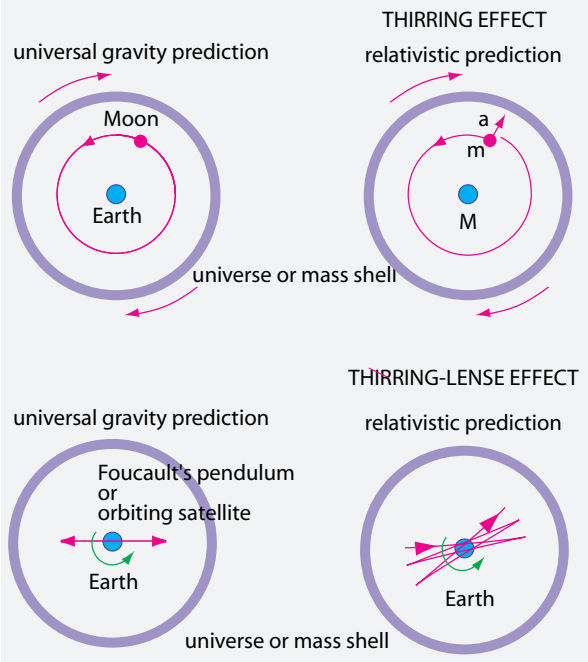


FIGURE 277 The Thirring and the Thirring–Lense effects

predictions.

In the first example, nowadays called the *Thirring effect*, centrifugal accelerations as well as Coriolis accelerations for masses in the interior of a rotating mass shell are predicted. Thirring showed that if an enclosing mass shell rotates, masses inside it are attracted towards the shell. The effect is very small; however, this prediction is in stark contrast to that of universal gravity, where a spherical mass shell – rotating or not – has no effect on masses in its interior. Can you explain this effect using the figure and the mattress analogy? Challenge 823 ny

The second effect, the *Thirring–Lense effect*,* is more famous. General relativity predicts that an oscillating Foucault pendulum, or a satellite circling the Earth in a polar orbit, does not stay precisely in a fixed plane relative to the rest of the universe, but that the rotation of the Earth drags the plane along a tiny bit. This *frame-dragging*, as the effect is also called, appears because the Earth in vacuum behaves like a rotating ball in a foamy mattress. When a ball or a shell rotates inside the foam, it partly drags the foam along with it. Similarly, the Earth drags some vacuum with it, and thus turns the plane of the pendulum. For the same reason, the Earth's rotation turns the plane of an orbiting satellite.

The Thirring–Lense or frame-dragging effect is extremely small. It was measured for the first time in 1998 by an Italian group led by Ignazio Ciufolini, and then again by the same group in the years up to 2004. They followed the motion of two special artificial

* Even though the order of the authors is Lense and Thirring, it is customary (but not universal) to stress the idea of Hans Thirring by placing him first.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 278 The LAGEOS satellites: metal spheres with a diameter of 60 cm, a mass of 407 kg, and covered with 426 retroreflectors (NASA)

satellites – shown in Figure 278 – consisting only of a body of steel and some Cat's-eyes. The group measured the satellite's motion around the Earth with extremely high precision, making use of reflected laser pulses. This method allowed this low-budget experiment to beat by many years the efforts of much larger but much more sluggish groups.* The results confirm the predictions of general relativity with an error of about 25 %.

Ref. 422

Frame dragging effects have also been measured in binary star systems. This is possible if one of the stars is a pulsar, because such stars send out regular radio pulses, e.g. every millisecond, with extremely high precision. By measuring the exact times when the pulses arrive on Earth, one can deduce the way these stars move and confirm that such subtle effects as frame dragging do take place.

Ref. 423

Gravitomagnetism**

Frame-dragging and the Thirring–Lense effect can be seen as special cases of gravitomagnetism. (We will show the connection below.) This approach to gravity, already studied in the nineteenth century by Holzmüller and by Tisserand, has become popular again in recent years, especially for its didactic advantages. As mentioned above, talking about a gravitational *field* is always an approximation. In the case of weak gravity, such as occurs in everyday life, the approximation is very good. Many relativistic effects can be described in terms of the gravitational field, without using the concept of space curvature or the metric tensor. Instead of describing the complete space-time mattress, the gravitational-field model only describes the deviation of the mattress from the flat state, by pretending that the deviation is a separate entity, called the gravitational field. But what is the relativistically correct way to describe the gravitational field?

Ref. 424

We can compare the situation to electromagnetism. In a relativistic description of electrodynamics, the electromagnetic field has an electric and a magnetic component. The electric field is responsible for the inverse-square Coulomb force. In the same way, in a relativistic description of (weak) gravity,*** the gravitational field has an gravitoelectric and a gravitomagnetic component. The gravitoelectric field is responsible for the inverse square acceleration of gravity; what we call the gravitational field in everyday life is the

Page 692

* One is the so-called Gravity Probe B satellite experiment, which should significantly increase the measurement precision; the satellite was put in orbit in 2005, after 30 years of planning.

** This section can be skipped at first reading.

*** The approximation requires low velocities, weak fields, and localized and stationary mass–energy distributions.

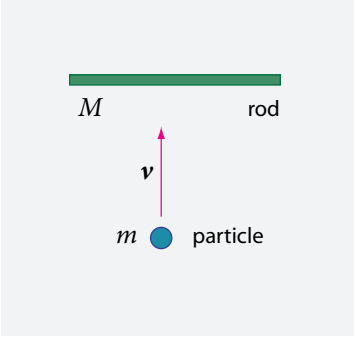

FIGURE 279 The reality of gravitomagnetism

gravitoelectric part of the full relativistic gravitational field.

In nature, all components of energy–momentum tensor produce gravity effects. In other words, it is not only mass and energy that produce a field, but also mass or energy *currents*. This latter case is called gravitomagnetism (or frame dragging). The name is due to the analogy with electrodynamics, where it is not only charge density that produces a field (the electric field), but also charge current (the magnetic field).

In the case of electromagnetism, the distinction between magnetic and electric field depends on the observer; each of the two can (partly) be transformed into the other. Ref. 425 Gravitation is exactly analogous. Electromagnetism provides a good indication as to how the two types of gravitational fields behave; this intuition can be directly transferred to gravity. In electrodynamics, the motion $\boldsymbol{x}(t)$ of a charged particle is described by the Page 677 Lorentz equation

$$m\ddot{\boldsymbol{x}} = q\boldsymbol{E} - q\dot{\boldsymbol{x}} \times \boldsymbol{b} \,. \tag{283}$$

In other words, the change of *speed* is due to electric fields $\boldsymbol{E}$, whereas magnetic fields $\boldsymbol{B}$ give a velocity-dependent change of the *direction* of velocity, without changing the speed itself. Both changes depend on the value of the charge q. In the case of gravity this expression becomes

$$m\ddot{\boldsymbol{x}} = m\boldsymbol{G} - m\dot{\boldsymbol{x}} \times \boldsymbol{H} \,. \tag{284}$$

The role of charge is taken by mass. In this expression we already know the field $\boldsymbol{G}$, given by

$$\boldsymbol{G} = \nabla\varphi = \nabla\frac{GM}{r} = -\frac{GM\boldsymbol{x}}{r^3} \,. \tag{285}$$

As usual, the quantity φ is the (scalar) potential. The field $\boldsymbol{G}$ is the usual gravitational field of universal gravity, produced by every mass, and in this context is called the *gravitoelectric field*; it has the dimension of an acceleration. Masses are the sources of the gravitoelectric field. The gravitoelectric field obeys $\Delta\boldsymbol{G} = -4\pi G\rho$, where ρ is the mass density. A *static* field $\boldsymbol{G}$ has no vortices; it obeys $\Delta \times \boldsymbol{G} = 0$.

It is not hard to show that if gravito*electric* fields exist, gravito*magnetic* fields must exist Ref. 426 as well; the latter appear whenever one changes from an observer at rest to a moving one. Page 692 (We will use the same argument in electrodynamics.) A particle falling perpendicularly

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

towards an infinitely long rod illustrates the point, as shown in Figure 279. An observer at rest with respect to the rod can describe the whole situation with gravitoelectric forces alone. A second observer, moving along the rod with constant speed, observes that the momentum of the particle *along the rod* also increases. This observer will thus not only measure a gravitoelectric field; he also measures a gravitomagnetic field. Indeed, a mass moving with velocity $\boldsymbol{v}$ produces a gravitomagnetic (3-) acceleration on a test mass m given by

Challenge 824 ny

$$m\boldsymbol{a} = -m\boldsymbol{v} \times \boldsymbol{H} \tag{286}$$

where, *almost* as in electrodynamics, the static *gravitomagnetic field* $\boldsymbol{H}$ obeys

$$\boldsymbol{H} = \nabla \times \boldsymbol{A} = 16\pi N \rho \boldsymbol{v} \tag{287}$$

where ρ is mass density of the source of the field and N is a proportionality constant. The quantity $\boldsymbol{A}$ is called the *gravitomagnetic vector potential*. In nature, there are no sources for the gravitomagnetic field; it thus obeys $\nabla \boldsymbol{H} = 0$. The gravitomagnetic field has dimension of inverse time, like an angular velocity.

Challenge 825 ny

When the situation in Figure 279 is evaluated, we find that the proportionality constant N is given by

$$N = \frac{G}{c^2} = 7.4 \cdot 10^{-28}\,\mathrm{m/kg}\,, \tag{288}$$

an extremely small value. We thus find that as in the electrodynamic case, the gravitomagnetic field is weaker than the gravitoelectric field by a factor of c^2. It is thus hard to observe. In addition, a second aspect renders the observation of gravitomagnetism even more difficult. In contrast to electromagnetism, in the case of gravity there is no way to observe *pure* gravitomagnetic fields (why?); they are always mixed with the usual, gravitoelectric ones. For these reasons, gravitomagnetic effects were measured for the first time only in the 1990s. We see that universal gravity is the approximation of general relativity that arises when all gravitomagnetic effects are neglected.

Challenge 826 s

In summary, *if a mass moves, it also produces a gravitomagnetic field*. How can one imagine gravitomagnetism? Let's have a look at its effects. The experiment of Figure 279 showed that a moving rod has the effect to slightly accelerate a test mass in the same direction. In our metaphor of the vacuum as a mattress, it looks as if a moving rod drags the vacuum along with it, as well as any test mass that happens to be in that region. Gravitomagnetism can thus be seen as vacuum dragging. Because of a widespread reluctance to think of the vacuum as a mattress, the expression *frame dragging* is used instead.

In this description, *all frame dragging effects are gravitomagnetic effects*. In particular, a gravitomagnetic field also appears when a large mass *rotates*, as in the Thirring–Lense effect of Figure 277. For an angular momentum $\boldsymbol{J}$ the gravitomagnetic field $\boldsymbol{H}$ is a dipole field; it is given by

$$\boldsymbol{H} = \nabla \times \boldsymbol{h} = \nabla \times \left(-2 \frac{\boldsymbol{J} \times \boldsymbol{x}}{r^3} \right) \tag{289}$$

exactly as in the electrodynamic case. The gravitomagnetic field around a spinning mass has three main effects.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

First of all, as in electromagnetism, a spinning test particle with angular momentum $\boldsymbol{S}$ feels a *torque* if it is near a large spinning mass with angular momentum $\boldsymbol{J}$. This torque $\boldsymbol{T}$ is given by

$$\boldsymbol{T} = \frac{\mathrm{d}\boldsymbol{S}}{\mathrm{d}t} = \tfrac{1}{2}\,\boldsymbol{S} \times \boldsymbol{H} \,. \tag{290}$$

The torque leads to the precession of gyroscopes. For the Earth, this effect is extremely small: at the North Pole, the precession has a conic angle of 0.6 milli-arcseconds and a rotation rate of the order of 10^{-10} times that of the Earth.

Since for a torque one has $\boldsymbol{T} = \dot{\boldsymbol{\Omega}} \times \boldsymbol{S}$, the dipole field of a large rotating mass with angular momentum $\boldsymbol{J}$ yields a second effect. An orbiting mass will experience precession of its orbital plane. Seen from infinity one gets, for an orbit with semimajor axis a and
Challenge 827 ny eccentricity e,

$$\dot{\boldsymbol{\Omega}} = -\frac{\boldsymbol{H}}{2} = -\frac{G}{c^2}\frac{\boldsymbol{J}}{|\boldsymbol{x}|^3} + \frac{G}{c^2}\frac{3(\boldsymbol{J}\boldsymbol{x})\boldsymbol{x}}{|\boldsymbol{x}|^5} = \frac{G}{c^2}\frac{2\boldsymbol{J}}{a^3(1-e^2)^{3/2}} \tag{291}$$

which is the prediction of Lense and Thirring.* The effect is extremely small, giving a change of only $8''$ per orbit for a satellite near the surface of the Earth. Despite this smallness and a number of larger effects disturbing it, Ciufolini's team have managed to
Ref. 422 confirm the result.

As a third effect of gravitomagnetism, a rotating mass leads to the precession of the periastron. This is a similar effect to the one produced by space curvature on orbiting masses even if the central body does not rotate. The rotation just reduces the precession due to space-time curvature. This effect has been fully confirmed for the famous binary pulsar PSR 1913+16, discovered in 1974, as well as for the 'real' double pulsar PSR J0737-3039, discovered in 2003. This latter system shows a periastron precession of 16.9°/a, the largest
Ref. 427 value observed so far.

The split into gravitoelectric and gravitomagnetic effects is thus a useful approximation to the description of gravity. It also helps to answer questions such as: How can gravity keep the Earth orbiting around the Sun, if gravity needs 8 minutes to get from
Challenge 829 ny the Sun to us? To find the answer, thinking about the electromagnetic analogy can help. In addition, the split of the gravitational field into gravitoelectric and gravitomagnetic components allows a simple description of gravitational waves.

Gravitational waves

One of the most fantastic predictions of physics is the existence of gravitational waves. Gravity waves** prove that empty space itself has the ability to move and vibrate. The basic idea is simple. Since space is elastic, like a large mattress in which we live, space should be able to oscillate in the form of propagating waves, like a mattress or any other elastic medium.

Challenge 828 ny * A homogeneous spinning sphere has an angular momentum given by $J = \frac{2}{5}M\omega R^2$.

** To be strict, the term 'gravity wave' has a special meaning: *gravity waves* are the surface waves of the sea, where gravity is the restoring force. However, in general relativity, the term is used interchangeably with 'gravitational wave'.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

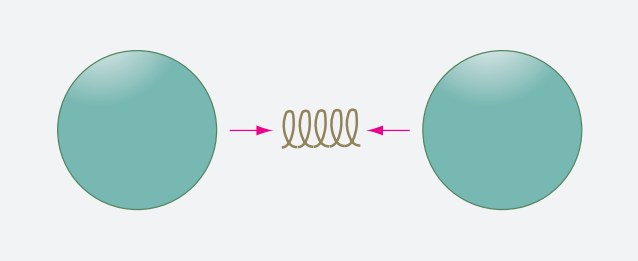

FIGURE 280 A Gedanken experiment showing the necessity of gravity waves

TABLE 52 The predicted spectrum of gravitational waves

FREQUENCY	WAVELENGTH	NAME	EXPECTED APPEARANCE
$< 10^{-4}$ Hz	> 3 Tm	extremely low frequencies	slow binary star systems, supermassive black holes
10^{-4} Hz–10^{-1} Hz	3 Tm–3 Gm	very low frequencies	fast binary star systems, massive black holes, white dwarf vibrations
10^{-1} Hz–10^{2} Hz	3 Gm–3 Mm	low frequencies	binary pulsars, medium and light black holes
10^{2} Hz–10^{5} Hz	3 Mm–3 km	medium frequencies	supernovae, pulsar vibrations
10^{5} Hz–10^{8} Hz	3 km–3 m	high frequencies	unknown; maybe future human-made sources
$> 10^{8}$ Hz	< 3 m		maybe unknown cosmological sources

Ref. 428

Starting from the existence of a maximum energy speed, Jørgen Kalckar and Ole Ulfbeck have given a simple argument for the necessity of gravitational. They studied two equal masses falling towards each other under the effect of gravitational attraction, and imagined a spring between them. Such a spring will make the masses bounce towards each other again and again. The central spring stores the kinetic energy from the falling masses. The energy value can be measured by determining the length by which the spring is compressed. When the spring expands again and hurls the masses back into space, the gravitational attraction will gradually slow down the masses, until they again fall towards each other, thus starting the same cycle again.

However, the energy stored in the spring must get smaller with each cycle. Whenever a sphere detaches from the spring, it is decelerated by the gravitational pull of the other sphere. Now, the value of this deceleration depends on the distance to the other mass; but since there is a maximal propagation velocity, the effective deceleration is given by the distance the other mass *had* when its gravity effect started out towards the second mass. For two masses departing from each other, the effective distance is thus somewhat smaller than the actual distance. In short, while departing, the real deceleration is *larger* than the one calculated without taking the time delay into account.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Similarly, when one mass falls back towards the other, it is accelerated by the other mass according to the distance it had when the gravity effect started moving towards it. Therefore, while approaching, the acceleration is *smaller* than the one calculated without time delay.

Therefore, the masses arrive with a *smaller* energy than they departed with. At every bounce, the spring is compressed a little less. The difference between these two energies is lost by each mass: it is taken away by space-time, in other words, it is radiated away as gravitational radiation. The same thing happens with mattresses. Remember that a mass deforms the space around it as a metal ball on a mattress deforms the surface around it. (However, in contrast to actual mattresses, there is no friction between the ball and the mattress.) If two metal balls repeatedly bang against each other and then depart again, until they come back together, they will send out surface waves on the mattress. Over time, this effect will reduce the distance that the two balls depart from each other after each bang. As we will see shortly, a similar effect has already been measured, where the two masses, instead of being repelled by a spring, were orbiting each other.

A simple mathematical description of gravity waves follows from the split into gravitomagnetic and gravitoelectric effects. It does not take much effort to extend gravitomagnetostatics and gravitoelectrostatics to *gravitodynamics*. Just as electrodynamics can be deduced from Coulomb's attraction when one switches to other inertial observers, gravitodynamics can be deduced from universal gravity. One gets the four equations

Ref. 429

Challenge 830 ny

$$\nabla \boldsymbol{G} = -4\pi G\rho \quad , \quad \nabla \times \boldsymbol{G} = -\frac{\partial \boldsymbol{H}}{\partial t}$$
$$\nabla \boldsymbol{H} = 0 \quad , \quad \nabla \times \boldsymbol{H} = -16\pi G\rho \boldsymbol{v} + \frac{N}{G}\frac{\partial \boldsymbol{G}}{\partial t} \,. \tag{292}$$

We have met two of these equations already. The two other equations are expanded versions of what we have encountered, taking time-dependence into account. Except for a factor of 16 instead of 4 in the last equation, the equations for gravitodynamics are the same as Maxwell's equations for electrodynamics.* These equations have a simple property: in vacuum, one can deduce from them a *wave equation* for the gravitoelectric and the gravitomagnetic fields $\boldsymbol{G}$ and $\boldsymbol{H}$. (It is not hard: try!) In other words, *gravity can behave like a wave: gravity can radiate*. All this follows from the expression of universal gravity when applied to moving observers, with the requirement that neither observers nor energy can move faster than c. Both the above argument involving the spring and the present mathematical argument use the same assumptions and arrive at the same conclusion.

Challenge 831 ny

* The additional factor reflects the fact that the ratio between angular momentum and energy (the 'spin') of gravity waves is different from that of electromagnetic waves. Gravity waves have spin 2, whereas electromagnetic waves have spin 1. Note that since gravity is universal, there can exist only a *single* kind of spin 2 radiation particle in nature. This is in strong contrast to the spin 1 case, of which there are several examples in nature.

By the way, the spin of radiation is a *classical* property. The *spin of a wave* is the ratio $E/L\omega$, where E is the energy, L the angular momentum, and ω is the angular frequency. For electromagnetic waves, this ratio is equal to 1; for gravitational waves, it is 2.

Ref. 430 Note that due to the approximation at the basis of the equations of gravitodynamics, the equations are *neither* gauge-invariant nor generally covariant.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

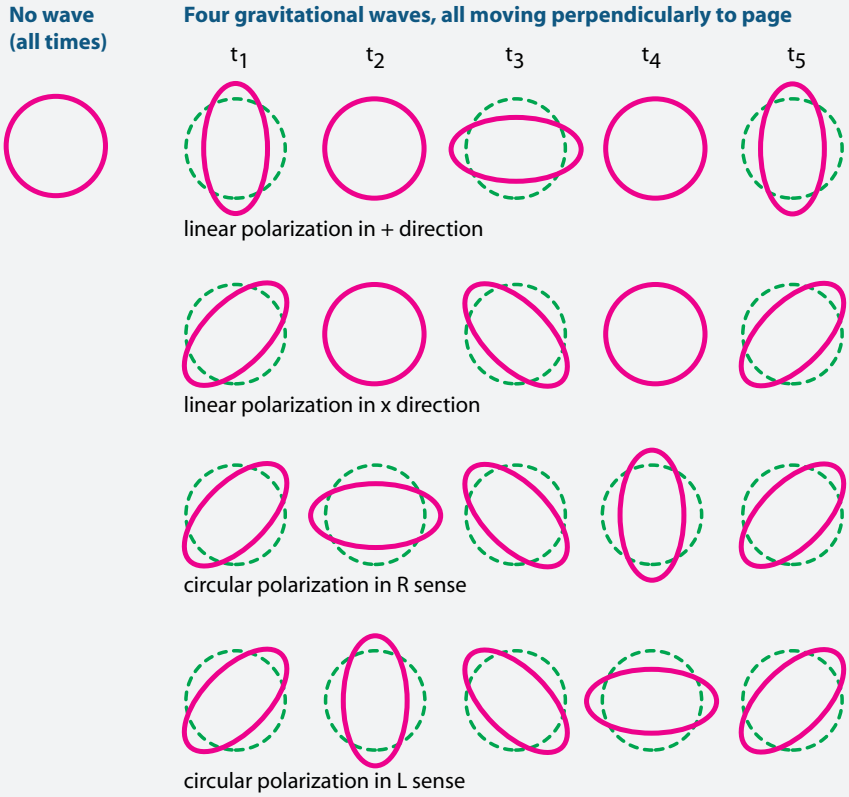

FIGURE 281 Effects on a circular or spherical body due to a plane gravitational wave moving in a direction perpendicular to the page

Challenge 832 e A few manipulations show that the speed of these waves is given by

$$c = \sqrt{\frac{G}{N}} \,. \tag{293}$$

Page 730 This result corresponds to the electromagnetic expression

$$c = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} \,. \tag{294}$$

The same letter has been used for the two speeds, as they are identical. Both influences travel with the speed common to all energy with vanishing rest mass. We note that this is, strictly speaking, a prediction: the speed of gravitational waves has not yet been measured. A claim from 2003 to have done so is disputed. Ref. 431

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 433 How should one imagine these waves? We sloppily said above that a gravitational wave corresponds to a surface wave of a mattress; now we have to do better and imagine that we live *inside* the mattress. Gravitational waves are thus moving and oscillating deformations of the mattress, i.e., of space. Like mattress waves, it turns out that gravity waves are *transverse*. Thus they can be polarized. (Surface waves on mattresses cannot, because in two dimensions there is no polarization.) Gravity waves can be polarized in two independent ways. The effects of a gravitational wave are shown in Figure 281, for both linear and circular polarization.* We note that the waves are invariant under a rotation by π and that the two linear polarizations differ by an angle $\pi/4$; this shows that the particles corresponding to the waves, the gravitons, are of spin 2. (In general, the classical radiation field for a spin S particle is invariant under a rotation by $2\pi/S$. In addition, the two orthogonal linear polarizations of a spin S particle form an angle $\pi/2S$. For the photon, for example, the spin is 1; indeed, its invariant rotation angle is 2π and the angle formed by the two polarizations is $\pi/2$.)

If we image empty space as a mattress that *fills* space, gravitational waves are wobbling deformations of the mattress. More precisely, Figure 281 shows that a wave of circular polarization has the same properties as a corkscrew advancing through the mattress. We will discover later on why the analogy between a corkscrew and a gravity wave with circular polarization works so well. Indeed, in the third last part of our adventure we will find a specific model of the space-time mattress material that automatically incorporates corkscrew waves (instead of the spin 1 waves shown by ordinary latex mattresses).

How does one produce gravitational waves? Obviously, masses must be accelerated. But how exactly? The conservation of energy forbids mass monopoles from varying in strength. We also know from universal gravity that a spherical mass whose radius oscillates would not emit gravitational waves. In addition, the conservation of momentum

* A (small amplitude) plane gravity wave travelling in the z-direction is described by a metric g given by

$$g = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & -1 + h_{xx} & h_{xy} & 0 \\ 0 & h_{xy} & -1 + h_{xx} & 0 \\ 0 & 0 & 0 & -1 \end{pmatrix} \tag{295}$$

where its two components, whose amplitude ratio determine the polarization, are given by

$$h_{ab} = B_{ab} \sin(kz - \omega t + \varphi_{ab}) \tag{296}$$

as in all plane harmonic waves. The amplitudes B_{ab}, the frequency ω and the phase φ are determined by the specific physical system. The general dispersion relation for the wave number k resulting from the wave equation is

$$\frac{\omega}{k} = c \tag{297}$$

and shows that the waves move with the speed of light.

In another gauge, a plane wave can be written as

$$g = \begin{pmatrix} c^2(1 + 2\varphi) & A_1 & A_2 & A_3 \\ A_1 & -1 + 2\varphi & h_{xy} & 0 \\ A_2 & h_{xy} & -1 + h_{xx} & 0 \\ A_3 & 0 & 0 & -1 \end{pmatrix} \tag{298}$$

where φ and $\boldsymbol{A}$ are the potentials such that $\boldsymbol{G} = \nabla\varphi - \frac{\partial \boldsymbol{A}}{c\partial t}$ and $\boldsymbol{H} = \nabla \times \boldsymbol{A}$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 833 ny forbids mass dipoles from changing.

As a result, only *changing quadrupoles* can emit waves.* For example, two masses in orbit around each other will emit gravitational waves. Also, any rotating object that is not cylindrically symmetric around its rotation axis will do so. As a result, rotating an arm leads to gravitational wave emission. Most of these statements also apply to masses Challenge 834 ny in mattresses. Can you point out the differences?

Einstein found that the amplitude h of waves at a distance r from a source is given, to Ref. 432 a good approximation, by the second derivative of the retarded quadrupole moment Q:

$$h_{ab} = \frac{2G}{c^4}\frac{1}{r}\mathrm{d}_{tt}Q^{\mathrm{ret}}_{ab} = \frac{2G}{c^4}\frac{1}{r}\mathrm{d}_{tt}Q_{ab}(t - r/c) \,. \tag{299}$$

This expression shows that the amplitude of gravity waves *decreases only with* $1/r$, in contrast to naive expectations. However, this feature is the same as for electromagnetic waves. In addition, the small value of the prefactor, $1.6 \cdot 10^{-44}\,\mathrm{Wm/s}$, shows that truly gigantic systems are needed to produce quadrupole moment changes that yield any detectable length variations in bodies. To be convinced, just insert a few numbers, keep- Challenge 835 ny ing in mind that the best present detectors are able to measure length changes down to $h = \delta l/l = 10^{-19}$. The production of detectable gravitational waves by humans is probably impossible.

Gravitational waves, like all other waves, transport energy.** If we apply the general formula for the emitted power P to the case of two masses m_1 and m_2 in circular orbits Ref. 393 around each other at distance l and get

$$P = -\frac{\mathrm{d}E}{\mathrm{d}t} = \frac{G}{45c^5}\dddot{Q}^{\mathrm{ret}}_{ab}\dddot{Q}^{\mathrm{ret}}_{ab} = \frac{32}{5}\frac{G}{c^5}\left(\frac{m_1 m_2}{m_1 + m_2}\right)^2 l^4\omega^6 \tag{300}$$

which, using Kepler's relation $4\pi^2 r^3/T^2 = G(m_1 + m_2)$, becomes

$$P = \frac{32}{5}\frac{G^4}{c^5}\frac{(m_1 m_2)^2(m_1 + m_2)}{l^5} \,. \tag{301}$$

Ref. 393 For elliptical orbits, the rate increases with the ellipticity, as explained by Goenner. Inserting the values for the case of the Earth and the Sun, we get a power of about 200 W, and a value of 400 W for the Jupiter–Sun system. These values are so small that their effect cannot be detected at all.

For all orbiting systems, the frequency of the waves is twice the orbital frequency, as Challenge 836 ny you might want to check. These low frequencies make it even more difficult to detect them.

As a result, the only observation of effects of gravitational waves to date is in binary

* A *quadrupole* is a symmetrical arrangement, on the *four* sides of a square, of four alternating poles. In gravitation, a monopole is a point-like or two spherical masses, and, since masses cannot be negative, a quadrupole is formed by *two* monopoles. A flattened sphere, such as the Earth, can be approximated by the sum of a monopole and a quadrupole. The same is valid for an elongated sphere.

Page 714 ** Gravitomagnetism and gravitoelectricity allow one to define a gravitational Poynting vector. It is as easy Ref. 426 to define and use as in the case of electrodynamics.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

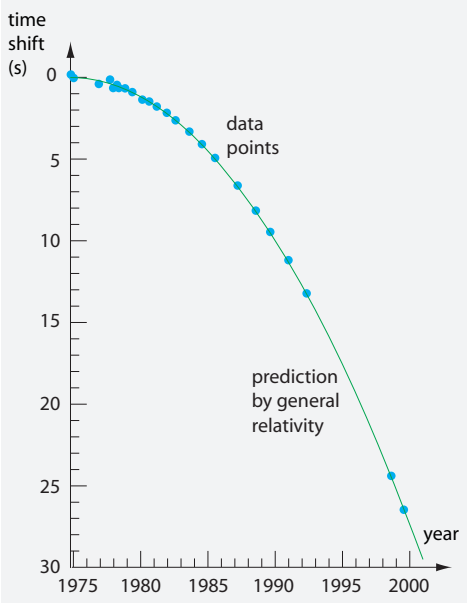

FIGURE 282 Comparison between measured time delay for the periastron of the binary pulsar PSR 1913+16 and the prediction due to energy loss by gravitational radiation

pulsars. Pulsars are small but extremely dense stars; even with a mass equal to that of the Sun, their diameter is only about 10 km. Therefore they can orbit each other at small distances and high speeds. Indeed, in the most famous binary pulsar system, PSR 1913+16, the two stars orbit each other in an amazing 7.8 h, even though their semimajor axis is about 700 Mm, just less than twice the Earth–Moon distance. Since their orbital speed is up to 400 km/s, the system is noticeably relativistic.

Pulsars have a useful property: because of their rotation, they emit extremely regular radio pulses (hence their name), often in millisecond periods. Therefore it is easy to follow their orbit by measuring the change of pulse arrival time. In a famous experiment, a team of astrophysicists led by Joseph Taylor* measured the speed decrease of the binary pulsar system just mentioned. Eliminating all other effects and collecting data for 20 years, they found a decrease in the orbital frequency, shown in Figure 282. The slowdown is due to gravity wave emission. The results exactly fit the prediction by general relativity, *without any adjustable parameter*. (You might want to check that the effect must be quadratic in time.) This is the only case so far in which general relativity has been tested up to $(v/c)^5$ precision. To get an idea of the precision, consider that this experiment detected a reduction of the orbital diameter of 3.1 mm per orbit, or 3.5 m per year! The measurements were possible only because the two stars in this system are neutron stars with small size, large velocities and purely gravitational interactions. The pulsar rotation period around its axis, about 59 ms, is known to eleven digits of precision, the orbital time of 7.8 h is known to ten digits and the eccentricity of the orbit to six digits.

The *direct* detection of gravitational waves is one of the aims of experimental general relativity. The race has been on since the 1990s. The basic idea is simple, as shown in

* In 1993 he shared the Nobel Prize in Physics for his life's work.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

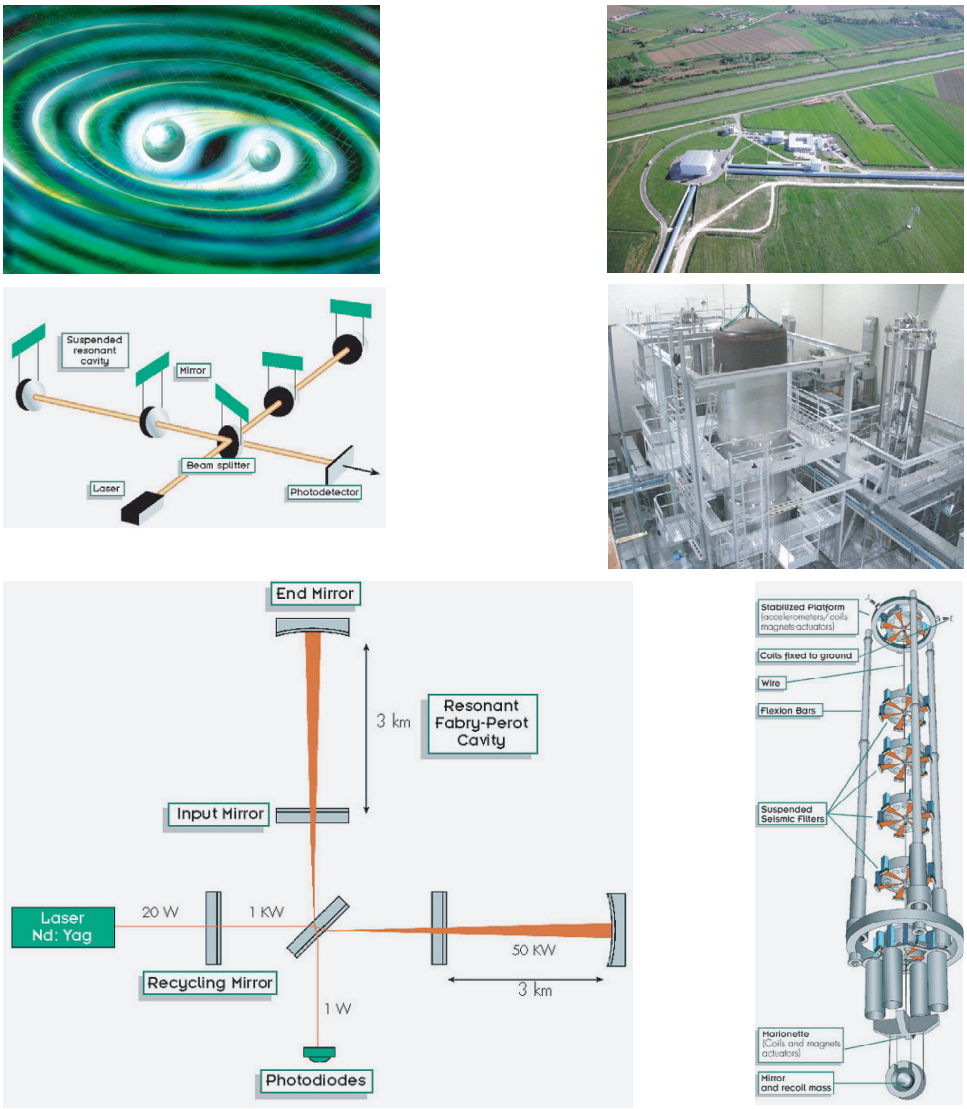

FIGURE 283 Detection of gravitational waves: an illustration of the merger of two black holes (top left) and the VIRGO detector in Cascina, Italy, with one of its huge mirror suspensions, the mirror suspension details, and two drawings of the laser interferometer (© INFN)

Figure 283: take four bodies, usually four mirrors, for which the line connecting one pair is perpendicular to the line connecting the other pair. Then measure the distance changes of each pair. If a gravitational wave comes by, one pair will increase in distance and the other will decrease, at the *same* time.

Since detectable gravitational waves cannot be produced by humans, wave detection first of all requires the patience to wait for a strong enough wave to come by. The merger of two black holes could be the source of such a strong gravitational wave, as also shown

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

in Figure 283. Secondly, a system able to detect length changes of the order of 10^{-22} or better is needed – in other words, a lot of money. Any detection is guaranteed to make the news on television.* Essential for a successful detection are the techniques to eliminate noise in the detection signal. The worlds's best noise reduction experts are all working on gravitational wave detectors.

It turns out that even for a body around a black hole, only about 6 % of the rest mass can be radiated away as gravitational waves; furthermore, most of the energy is radiated during the final fall into the black hole, so that only quite violent processes, such as black hole collisions, are good candidates for detectable gravity wave sources.

Challenge 839 r Ref. 431 Gravitational waves are a fascinating area of study. They still provide many topics to explore. For example: can you find a method to measure their speed? A well-publicized but disputed claim appeared in 2003. Indeed, any correct measurement that does not simply use two spaced detectors of the type of Figure 283 would be a scientific sensation.

Challenge 840 ny For the time being, another question on gravitational waves remains open: If all change is due to motion of particles, as the Greeks maintained, how do gravity waves fit into the picture? If gravitational waves were made of particles, space-time would also have to be. We have to wait until the beginning of the final part of our ascent to say more.

Bending of light and radio waves

As we know from above, gravity also influences the motion of light. A distant observer measures a changing value for the light speed v near a mass. (Measured at his own location, the speed of light is of course always c.) It turns out that a distant observer measures a *lower* speed, so that for him, gravity has the same effects as a dense optical medium. It takes only a little bit of imagination to see that this effect will thus *increase* the bending of light near masses already deduced in 1801 by Soldner for universal gravity.

Ref. 437 The following is a simple way to calculate the effect. As usual, we use the coordinate system of flat space-time at infinity. The idea is to do all calculations to first order, as the value of the bending is very small. The angle of deflection α, to first order, is simply

$$\alpha = \int_{-\infty}^{\infty} \frac{\partial v}{\partial x} \mathrm{d}y \,, \tag{302}$$

Challenge 841 ny where v is the speed of light measured by a distant observer. (Can you confirm this?) The next step is to use the Schwarzschild metric

$$\mathrm{d}\tau^2 = \left(1 - \frac{2GM}{rc^2}\right)\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{c^2 - \frac{2GM}{r}} - \frac{r^2}{c^2}\mathrm{d}\varphi^2 \tag{303}$$

Challenge 842 ny and transform it into (x, y) coordinates to first order. That gives

$$\mathrm{d}\tau^2 = \left(1 - \frac{2GM}{rc^2}\right)\mathrm{d}t^2 - \left(1 + \frac{2GM}{rc^2}\right)\frac{1}{c^2}(\mathrm{d}x^2 + \mathrm{d}y^2) \tag{304}$$

Ref. 436 Challenge 838 ny * The topic of gravity waves is full of interesting sidelines. For example, can gravity waves be used to power a rocket? Yes, maintain Bonnor and Piper. You might ponder the possibility yourself.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

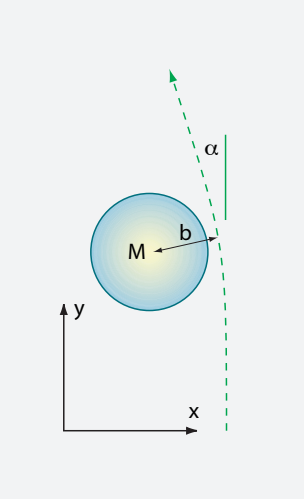

FIGURE 284 Calculating the bending of light by a mass

which again to first order leads to

$$\frac{\partial v}{\partial x} = \left(1 - \frac{2GM}{rc^2}\right) c \,. \tag{305}$$

This confirms what we know already, namely that distant observers see light *slowed down* when passing near a mass. Thus we can also speak of a height-dependent index of refraction. In other words, constant *local* light speed leads to a *global* slowdown.

Challenge 843 ny

Inserting the last result in (302) and using a clever substitution, we get a deviation angle α given by

$$\alpha = \frac{4GM}{c^2}\frac{1}{b} \tag{306}$$

where the distance b is the so-called *impact parameter* of the approaching light beam. The resulting deviation angle α is *twice* the result we found for universal gravity. For a beam just above the surface of the Sun, the result is the famous value of $1.75''$ which was confirmed by the measurement expedition of 1919. (How did they measure the deviation angle?) This was the experiment that made Einstein famous, as it showed that universal gravity is wrong. In fact, Einstein was lucky. Two earlier expeditions organized to measure the value had failed. In 1912, it was impossible to take data because of rain, and in 1914 in Crimea, scientists were arrested (by mistake) as spies, because the world war had just begun. But in 1911, Einstein had already published an *incorrect* calculation, giving only the Soldner value with half the correct size; only in 1915, when he completed general relativity, did he find the correct result. Therefore Einstein became famous only because of the failure of the two expeditions that took place before he published his correct calculation.

Page 161
Challenge 844 ny
Ref. 438
Page 161

For high-precision experiments around the Sun, it is more effective to measure the bending of radio waves, as they encounter fewer problems when they propagate through

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the solar corona. So far, over a dozen independent experiments have done so, using radio sources in the sky which lie on the path of the Sun. They have confirmed general relativity's prediction within a few per cent.

Ref. 414, Ref. 392
Ref. 393

So far, bending of radiation has also been observed near Jupiter, near certain stars, near several galaxies and near galaxy clusters. For the Earth, the angle is at most 3 nrad, too small to be measured yet, even though this may be feasible in the near future. There is a chance to detect this value if, as Andrew Gould proposes, the data of the satellite Hipparcos, which was taking precision pictures of the night sky for many years, are analysed properly in the future.

Page 595

Of course, the bending of light also confirms that in a triangle, the sum of the angles does not add up to π (two right angles), as is predicted later for curved space. (What is the sign of the curvature?)

Page 543
Challenge 845 ny

Time delay

The above calculation of the bending of light near masses shows that for a distant observer, light is slowed down near a mass. Constant *local* light speed leads to a *global* light speed slowdown. If light were not slowed down near a mass, it would have to go faster than c for an observer near the mass!* In 1964, Irwin Shapiro had the idea to measure this effect. He proposed two methods. The first was to send radar pulses to Venus, and measure the time taken for the reflection to get back to Earth. If the signals pass near the Sun, they will be delayed. The second was to use an artificial satellite communicating with Earth.

Ref. 439

The first measurement was published in 1968, and directly confirmed the prediction of general relativity within experimental errors. All subsequent tests of the same type, such as the one shown in Figure 285, have also confirmed the prediction within experimental errors, which nowadays are of the order of one part in a thousand. The delay has also been measured in binary pulsars, as there are a few such systems in the sky for which the line of sight lies almost precisely in the orbital plane.

Ref. 440
Ref. 441

The simple calculations presented here suggest a challenge: Is it also possible to describe *full* general relativity – thus gravitation in *strong* fields – as a change of the speed of light with position and time induced by mass and energy?

Challenge 847 ny

Effects on orbits

Astronomy allows precise measurements of motions. So, Einstein first of all tried to apply his results to the motion of planets. He looked for deviations of their motions from the predictions of universal gravity. Einstein found such a deviation: the precession of the perihelion of Mercury. The effect is shown in Figure 286. Einstein said later that the moment he found out that his calculation for the precession of Mercury matched observations was one of the happiest moments of his life.

The calculation is not difficult. In universal gravity, orbits are calculated by setting

* A nice exercise is to show that the bending of a slow particle gives the Soldner value, whereas with increasing speed, the value of the bending approaches twice that value. In all these considerations, the rotation of the mass has been neglected. As the effect of frame dragging shows, rotation also changes the deviation angle; however, in all cases studied so far, the influence is below the detection threshold.

Challenge 846 e

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

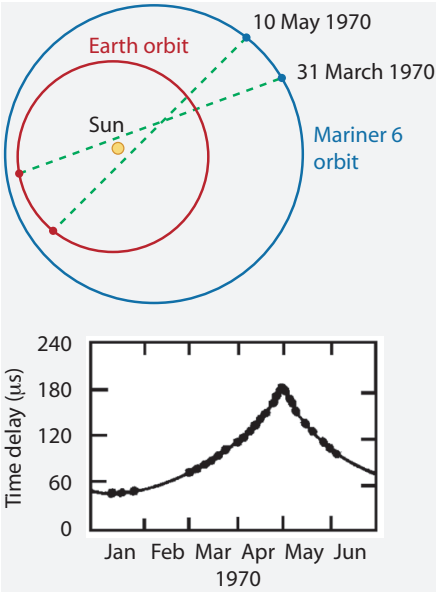

FIGURE 285 Time delay in radio signals – one of the experiments by Irwin Shapiro

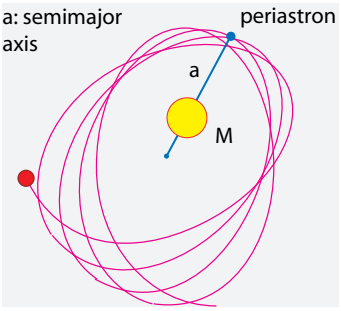

FIGURE 286 The orbit around a central body in general relativity

$a_{\text{grav}} = a_{\text{centri}}$, in other words, by setting $GM/r^2 = \omega^2 r$ and fixing energy and angular momentum. The mass of the orbiting satellite does not appear explicitly.

In general relativity, the mass of the orbiting satellite is made to disappear by rescaling energy and angular momentum as $e = E/mc^2$ and $j = J/m$. Next, the space curvature needs to be included. We use the Schwarzschild metric (303) mentioned above to deduce that the initial condition for the energy e, together with its conservation, leads to a relation between proper time τ and time t at infinity:

Ref. 392, Ref. 393
Page 506
Challenge 848 e

$$\frac{\mathrm{d}t}{\mathrm{d}\tau} = \frac{e}{1 - 2GM/rc^2} \,, \tag{307}$$

whereas the initial condition on the angular momentum j and its conservation imply that

$$\frac{\mathrm{d}\varphi}{\mathrm{d}\tau} = \frac{j}{r^2} \,. \tag{308}$$

These relations are valid for any particle, whatever its mass m. Inserting all this into the Schwarzschild metric, we find that the motion of a particle follows

$$\left(\frac{\mathrm{d}r}{c\mathrm{d}\tau}\right)^2 + V^2(j, r) = e^2 \tag{309}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

where the effective potential V is given by

$$V^2(J,r) = (1 - \frac{2GM}{rc^2})(1 + \frac{j^2}{r^2c^2}) \,. \tag{310}$$

Challenge 849 ny
Challenge 850 e
The expression differs slightly from the one in universal gravity, as you might want to check. We now need to solve for $r(\varphi)$. For *circular* orbits we get *two* possibilities

$$r_\pm = \frac{6GM/c^2}{1 \pm \sqrt{1 - 12(\frac{GM}{cj})^2}} \tag{311}$$

where the minus sign gives a stable and the plus sign an unstable orbit. If $cj/GM < 2\sqrt{3}$, no stable orbit exists; the object will impact the surface or, for a black hole, be swallowed. There is a stable circular orbit *only* if the angular momentum j is larger than $2\sqrt{3}GM/c$. We thus find that in general relativity, in contrast to universal gravity, there is a *smallest* stable circular orbit. The radius of this smallest stable circular orbit is $6GM/c^2 = 3R_S$.

What is the situation for *elliptical* orbits? Setting $u = 1/r$ in (309) and differentiating, the equation for $u(\varphi)$ becomes

$$u' + u = \frac{GM}{j^2} + \frac{3GM}{c^2}u^2 \,. \tag{312}$$

Challenge 851 e
Without the nonlinear correction due to general relativity on the far right, the solutions are the famous *conic sections*

$$u_0(\varphi) = \frac{GM}{j^2}(1 + \varepsilon\cos\varphi) \,, \tag{313}$$

i.e., ellipses, parabolas or hyperbolas. The type of conic section depends on the value of the parameter ε, the so-called *eccentricity*. We know the shapes of these curves from
Page 155
universal gravity. Now, general relativity introduces the nonlinear term on the right-hand side of equation (312). Thus the solutions are not conic sections any more; however, as
Challenge 852 e
the correction is small, a good approximation is given by

$$u_1(\varphi) = \frac{GM}{j^2}\left(1 + \varepsilon\cos(\varphi - \frac{3G^2M^2}{j^2c^2}\varphi)\right) \,. \tag{314}$$

The hyperbolas and parabolas of universal gravity are thus slightly deformed. Instead of elliptical orbits we get the famous rosetta path shown in Figure 286. Such a path is above all characterized by a periastron shift. The *periastron*, or *perihelion* in the case of the Sun, is the nearest point to the central body reached by an orbiting body. The periastron turns
Challenge 853 e
around the central body by an angle

$$\alpha \approx 6\pi\frac{GM}{a(1-\varepsilon^2)c^2} \tag{315}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

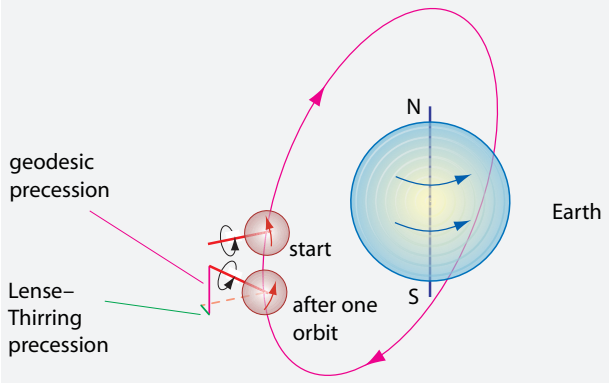

FIGURE 287 The geodesic effect

for every orbit, where a is the *semimajor axis*. For Mercury, the value is 43″ per century. Around 1900, this was the only known effect that was unexplained by universal gravity; when Einstein's calculation led him to exactly that value, he was overflowing with joy for many days.

To be sure about the equality between calculation and experiment, all other effects leading to rosetta paths must be eliminated. For some time, it was thought that the quadrupole moment of the Sun could be an alternative source of this effect; later measurements ruled out this possibility.

In the meantime, the perihelion shift has been measured also for the orbits of Icarus, Venus and Mars around the Sun, as well as for several binary star systems. In binary pul-
Ref. 441 sars, the periastron shift can be as large as several degrees per year. In all cases, expression (315) describes the motion within experimental errors.

We note that even the rosetta orbit itself is not really stable, due to the emission of gravitational waves. But in the solar system, the power lost this way is completely negli-
Page 530 gible even over thousands of millions of years, as we saw above, so that the rosetta path remains a good description of observations.

The geodesic effect

When a pointed body orbits a central mass m at distance r, the direction of the tip will not be the same after a full orbit. This effect exists only in general relativity. The angle α describing the direction change is given by

$$\alpha = 2\pi\left(1 - \sqrt{1 - \frac{3Gm}{rc^2}}\right) \approx \frac{3\pi Gm}{rc^2} \,. \tag{316}$$

The angle change is called the *geodesic effect* – 'geodetic' in other languages. It is a further consequence of the split into gravitoelectric and gravitomagnetic fields, as you may want
Challenge 854 e to show. Obviously, it does not exist in universal gravity.

In cases where the pointing of the orbiting body is realized by an intrinsic rotation, such as a spinning satellite, the geodesic effect produces a *precession* of the axis. Thus the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

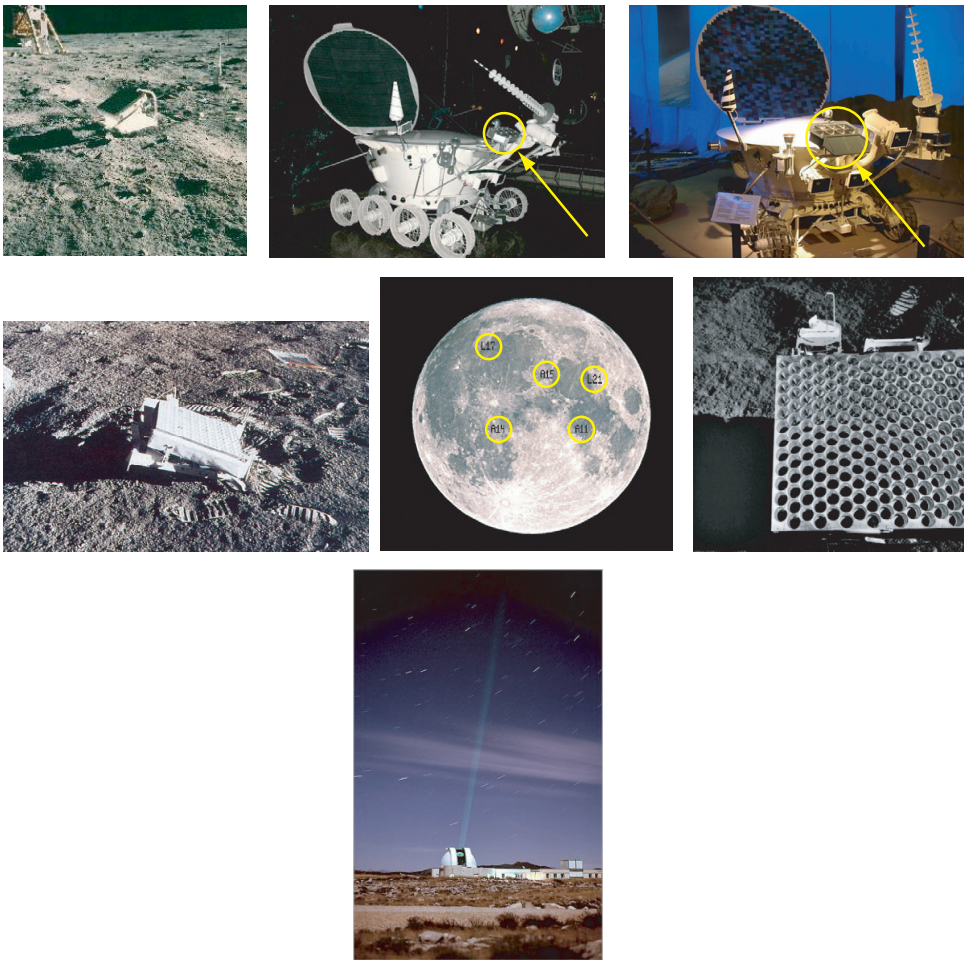

FIGURE 288 The lunar retroreflectors deposited by Apollo 11 (top left), Lunokhod (top centre and right), Apollo 14 (middle left) and Apollo 15 (middle right) together with their locations on the Moon and a telescope performing a distance measurement (© NASA, Observatoire de la Côte d'Azur)

effect is comparable to spin–orbit coupling in atomic theory. (The Thirring–Lense effect mentioned above is analogous to spin–spin coupling.)

Ref. 442 The geodesic effect, or geodesic precession, was predicted by Willem de Sitter in 1916; in particular, he proposed detecting that the Earth–Moon system would change its pointing direction in its fall around the Sun. The effect is tiny; for the axis of the Moon the precession angle is about 0.019 arcsec per year. The effect was first detected in 1987 by an Ref. 443 Italian team for the Earth–Moon system, through a combination of radio-interferometry and lunar ranging, making use of the Cat's-eyes, shown in Figure 288, deposited by Lunokhod and Apollo on the Moon. Experiments to detect the geodesic effect in artificial satellites are also under way.

At first sight, geodesic precession is similar to the Thomas precession found in special Page 437 relativity. In both cases, a transport along a closed line results in the loss of the original

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

direction. However, a careful investigation shows that Thomas precession can be *added* to geodesic precession by applying some additional, non-gravitational interaction, so the analogy is shaky.

This completes our discussion of weak gravity effects. We now turn to strong gravity, where curvature cannot be neglected and where the fun is even more intense.

Curiosities and fun challenges about weak fields

Challenge 855 ny Is there a static, oscillating gravitational field?

* *

If one explores the options for the speed of gravitational waves, there is an interesting connection. If the speed of gravitational waves were *smaller* than the speed of light, moving bodies that move almost as rapidly as the speed of light, like cosmic ray particles, would be slowed down by emitting *Vavilov–Čerenkov radiation*, until they reach the lower speed. This is not observed.

Page 410

If on the other hand, the speed of gravitational waves were *larger* than that of light, the waves would not obey causality or the second principle of thermodynamics. In short, gravitational waves, if they exist, must propagate with the speed of light. (A speed very near to the speed of light might also be possible.)

* *

Challenge 856 ny Are narrow beams of gravitational waves, analogous to beams of light, possible?

* *

Challenge 857 ny Would two parallel beams of gravitational waves attract each other?

How is curvature measured?

We have seen that in the precise description of gravity, motion depends on space-time curvature. In order to quantify this idea, we first of all need to describe curvature itself as accurately as possible. To clarify the issue, we will start the discussion in two dimensions, and then move to three and four dimensions.

Obviously, a flat sheet of paper has no curvature. If we roll it into a cone or a cylinder, it gets what is called *extrinsic curvature*; however, the sheet of paper still looks flat for any two-dimensional animal living on it – as approximated by an ant walking over it. In other words, the *intrinsic curvature* of the sheet of paper is zero even if the sheet as a whole is extrinsically curved. (Can a one-dimensional space have intrinsic curvature? Is a torus intrinsically curved?)

Challenge 858 s

Intrinsic curvature is thus the stronger concept, measuring the curvature which can be observed even by an ant. (All intrinsically curved surfaces are also extrinsically curved.) The surface of the Earth, the surface of an island, or the slopes of a mountain* are intrinsically curved. Whenever we talk about curvature in general relativity, we always mean

Challenge 859 e * Unless the mountain has the shape of a perfect cone. Can you confirm this?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

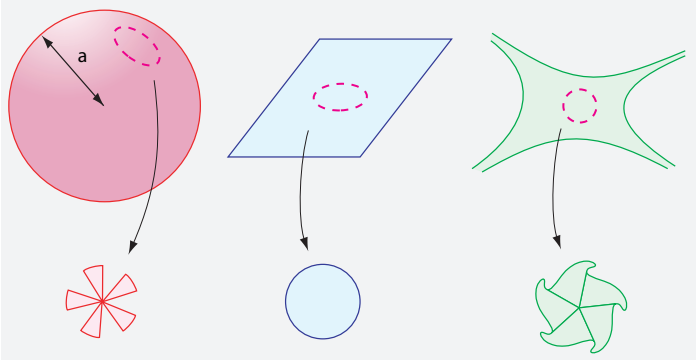

FIGURE 289 Positive, vanishing and negative curvature in two dimensions

intrinsic curvature, since any observer in nature is by definition in the same situation as an ant on a surface: their experience, their actions and plans always only concern their closest neighbourhood in space and time.

But how can an ant determine whether it lives on an intrinsically curved surface?* One way is shown in Figure 289. The ant can check whether either the circumference of a circle or its area bears a Euclidean relation to the measured radius. She can even use the difference between the measured and the Euclidean values as a measure for the local intrinsic curvature, if she takes the limit for vanishingly small circles and if she normalizes the values correctly. In other words, the ant can imagine to cut out a little disc around the point she is on, to iron it flat and to check whether the disc would tear or produce folds. Any two-dimensional surface is intrinsically curved whenever ironing is not able to make a flat street map out of it. The 'density' of folds or tears is related to the curvature.

This means that we can recognize intrinsic curvature also by checking whether two parallel lines stay parallel, approach each other, or depart from each other. In the first case, such as lines on a paper cylinder, the surface is said to have *vanishing* intrinsic curvature; a surface with approaching parallels, such as the Earth, is said to have *positive* curvature, and a surface with diverging parallels, such as a saddle, is said to have *negative* curvature. In short, positive curvature means that we are more restricted in our movements, negative that we are less restricted. A *constant* curvature even implies being locked in a finite space. You might want to check this with Figure 289.

The third way to measure curvature uses triangles. On curved surfaces the sum of angles in a triangle is either larger or smaller than π (two right angles).

Ref. 444 Let us see how we can quantify curvature. First a question of vocabulary: a sphere with radius a is said, by definition, to have an intrinsic curvature $K = 1/a^2$. Therefore a plane has zero curvature. You might check that for a circle on a sphere, the measured Challenge 860 e radius r, circumference C, and area A are related by

$$C = 2\pi r\left(1 - \frac{K}{6}r^2 + \ldots\right) \quad \text{and} \quad A = \pi r^2\left(1 - \frac{K}{12}r^2 + \ldots\right) \tag{317}$$

* Note that the answer to this question also tells us how to distinguish real curvature from curved coordinate systems on a flat space. This question is often asked by those approaching general relativity for the first time.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

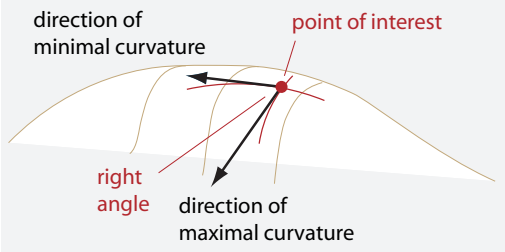

FIGURE 290 The maximum and minimum curvature of a curved surface

where the dots imply higher-order terms. This allows one to define the intrinsic curvature K, also called the *Gaussian* curvature, for a general point on a two-dimensional surface in either of the following two equivalent ways:

$$K = 6 \lim_{r\to 0}(1 - \frac{C}{2\pi r})\frac{1}{r^2} \quad \text{or} \quad K = 12 \lim_{r\to 0}(1 - \frac{A}{\pi r^2})\frac{1}{r^2} \,. \tag{318}$$

These expressions allow an ant to measure the intrinsic curvature at each point for any smooth surface.* From now on in this text, *curvature* will always mean *intrinsic* curvature. Note that the curvature can be different from place to place, and that it can be positive, as for an egg, or negative, as for the part of a torus nearest to the hole. A saddle is another example of the latter case, but, unlike the torus, its curvature changes along all directions. In fact, it is not possible at all to fit a two-dimensional surface of *constant* negative curvature inside three-dimensional space; one needs at least four dimensions, as you can find out if you try to imagine the situation.

Challenge 862 e

For any surface, at *every* point, the direction of maximum curvature and the direction of minimum curvature are *perpendicular* to each other. This relationship, shown in Figure 290, was discovered by Leonhard Euler in the eighteenth century. You might want to check this with a tea cup, with a sculpture by Henry Moore, or with any other curved object from your surroundings, such as a Volkswagen Beetle. The Gaussian curvature K defined in (318) is in fact the product of the two corresponding inverse curvature radii. Thus, even though line curvature is not an intrinsic property, this special product is. Gaussian curvature is a measure of the intrinsic curvature. Intrinsic measures of curvature are needed if one is forced to stay inside the surface or space one is exploring. Physicists are thus particularly interested in Gaussian curvature and its higher-dimensional analogues.

Challenge 863 e

For *three*-dimensional 'surfaces', the issue is a bit more involved. First of all, we have difficulties imagining the situation. But we can still accept that the curvature of a small disc around a point will depend on its orientation. Let us first look at the simplest case. If the curvature at a point is the same in all directions, the point is called *isotropic*. We can

* If the n-dimensional volume of a sphere is written as $V_n = C_n r^n$ and its $(n-1)$-dimensional 'surface' as $O_n = nC_n r^{n-1}$, one can generalize the expressions for curvature to

Ref. 445

$$K = 3(n+2) \lim_{r\to 0}(1 - \frac{V_n}{C_n r^n})\frac{1}{r^2} \quad \text{or} \quad K = 3n \lim_{r\to 0}(1 - \frac{O_n}{nC_n r^{n-1}})\frac{1}{r^2} \,, \tag{319}$$

Challenge 861 ny

as shown by Vermeil. A famous riddle is to determine the number C_n.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

imagine a small sphere around that point. In this special case, in three dimensions, the relation between the measured radius r and the measured surface area A and volume V of the sphere lead to

Challenge 864 ny

$$A = 4\pi r^2(1 - \frac{K}{3}r^2 + \ldots) \quad \text{and} \quad V = \frac{4\pi}{3}r^3(1 - \frac{K}{5}r^2 + \ldots) \,, \tag{320}$$

where K is the curvature for an isotropic point. This leads to

$$K = 3\lim_{r\to 0}(1 - \frac{A}{4\pi r^2})\frac{1}{r^2} = 6\lim_{r\to 0}\frac{r - \sqrt{A/4\pi}}{r^3} = 6\lim_{r\to 0}\frac{r_{\text{excess}}}{r^3} \,, \tag{321}$$

defining the *excess radius* as $r_{\text{excess}} = r - \sqrt{A/4\pi}$. We thus find that for a three-dimensional space, *the average curvature is six times the excess radius of a small sphere divided by the cube of the radius*. A positive curvature is equivalent to a positive excess radius, and similarly for vanishing and negative cases.

Of course, a curvature value defined in this way is only an average over all possible directions. The precise definition of curvature involves a disc. For points that are not isotropic, the value yielded by a disc will *differ* from the value calculated by using a sphere, as it will depend on the *orientation* of the disc. In fact, there is a relationship between all possible disc curvatures at a given point; taken together, they must form a tensor. (Why?) For a full description of curvature, we thus have to specify, as for any tensor in three dimensions, the main curvature values in three orthogonal directions.*

Challenge 865 ny

What are the curvature values in the space around us? Already in 1827, the mathematician and physicist Carl-Friedrich Gauß** is said to have checked whether the three angles formed by three mountain peaks near his place of residence added up to π. Nowadays we know that the deviation δ from the angle π on the surface of a body of mass M and radius r is given by

$$\delta = \pi - (\alpha + \beta + \gamma) \approx A_{\text{triangle}}K = A_{\text{triangle}}\frac{GM}{r^3c^2} \,. \tag{322}$$

* These three disc values are not independent however, since together, they must yield the just-mentioned average volume curvature K. In total, there are thus *three* independent scalars describing the curvature in three dimensions (at each point). With the metric tensor g_{ab} and the Ricci tensor R_{ab} to be introduced below, one possibility is to take for the three independent numbers the values $R = -2K$, $R_{ab}R^{ab}$ and $\det R/\det g$.

** Carl-Friedrich Gauß (b. 1777 Braunschweig, d. 1855 Göttingen), German mathematician. Together with the Leonhard Euler, the most important mathematician of all times. A famous enfant prodige, when he was 19 years old, he constructed the regular heptadecagon with compass and ruler (see www.mathworld.wolfram.com/Heptadecagon.html). He was so proud of this result that he put a drawing of the figure on his tomb. Gauss produced many results in number theory, topology, statistics, algebra, complex numbers and differential geometry which are part of modern mathematics and bear his name. Among his many accomplishments, he produced a theory of curvature and developed non-Euclidean geometry. He also worked on electromagnetism and astronomy.

Gauss was a difficult character, worked always for himself, and did not found a school. He published little, as his motto was: pauca sed matura. As a consequence, when another mathematician published a new result, he regularly produced a notebook in which he had noted the very same result already years before. His notebooks are now available online at www.sub.uni-goettingen.de.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

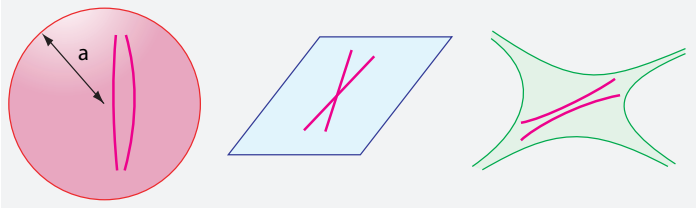

FIGURE 291 Positive, vanishing and negative curvature (in two dimensions) and geodesic behaviour

This expression is typical for hyperbolic geometries. For the case of mathematical negative curvature K, the first equality was deduced by Johann Lambert (1728–1777). However, it was Einstein who discovered that the negative curvature K is related to the mass and gravitation of a body. For the case of the Earth and typical mountain distances, the angle δ is of the order of 10^{-14} rad. Gauss had no chance to detect any deviation, and in fact he detected none. Even today, studies with lasers and high-precision apparatus have detected no deviation yet – on Earth. The right-hand factor, which measures the curvature of space-time on the surface of the Earth, is simply too small. But Gauss did not know, as we do today, that gravity and curvature go hand in hand.

Curvature and space-time

> Notre tête est ronde pour permettre à la pensée de changer de direction.*
>
> Francis Picabia

In nature, with *four* space-time dimensions, specifying curvature requires a more involved approach. First of all, the use of space-time coordinates automatically introduces the speed of light c as limit speed, which is a central requirement in general relativity. Furthermore, the number of dimensions being four, we expect a value for an average curvature at a point, defined by comparing the 4-volume of a 4-sphere in space-time with the one deduced from the measured radius; then we expect a set of 'almost average' curvatures defined by 3-volumes of 3-spheres in various orientations, plus a set of 'low-level' curvatures defined by usual 2-areas of usual 2-discs in even more orientations. Obviously, we need to bring some order to bear on this set, and we need to avoid the double counting we encountered in the case of three dimensions.

Fortunately, physics can help to make the mathematics easier. We start by defining what we mean by curvature of space-time. Then we will define curvatures for discs of various orientations. To achieve this, we interpret the definition of curvature in another way, which allows us to generalize it to time as well. Figure 291 illustrates the fact that the curvature K also describes how geodesics *diverge*. Geodesics are the straightest paths on a surface, i.e., those paths that a tiny car or tricycle would follow if it drove on the surface keeping the steering wheel straight.

Challenge 866 e If a space is curved, the separation s will increase along the geodesics as

* 'Our head is round in order to allow our thougths to change direction.' Francis Picabia (b. 1879 Paris, d. 1953 Paris) French dadaist and surrealist painter.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$\frac{\mathrm{d}^2 s}{\mathrm{d}l^2} = -Ks + \text{higher orders} \tag{323}$$

where l measures the length along the geodesic, and K is the curvature, in other words, the inverse squared curvature radius. In space-time, this relation is extended by substituting proper time (times the speed of light) for proper length. Thus separation and curvature are related by

$$\frac{\mathrm{d}^2 s}{\mathrm{d}\tau^2} = -Kc^2 s + \text{higher orders} \,. \tag{324}$$

But this is the definition of an acceleration. In other words, what in the purely spatial case is described by *curvature*, in the case of space-time becomes the *relative acceleration* of two particles freely falling from nearby points. Indeed, we have encountered these accelerations already: they describe tidal effects. In short, space-time curvature and tidal effects are precisely the same.

Page 158

Obviously, the magnitude of tidal effects, and thus of curvature, will depend on the orientation – more precisely on the orientation of the space-time plane formed by the two particle velocities. The definition also shows that K is a tensor, so that later on we will have to add indices to it. (How many?) The fun is that we can avoid indices for a while by looking at a special combination of spatial curvatures. If we take three planes in space, all orthogonal to each other and intersecting at a given point, the *sum* of the three so-called *sectional* curvature values does *not* depend on the observer. (This corresponds to the tensor trace.) Can you confirm this, by using the definition of the curvature just given?

Challenge 867 ny

Ref. 446

Challenge 868 ny

The sum of the three sectional curvatures defined for mutually orthogonal planes $K_{(12)}$, $K_{(23)}$ and $K_{(31)}$, is related to the excess radius defined above. Can you find out how?

Challenge 869 ny

If a surface has *constant* (intrinsic) curvature, i.e., the same curvature at all locations, geometrical objects can be moved around without deforming them. Can you picture this?

Challenge 870 e

In summary, curvature is not such a difficult concept. It describes the *deformation* of space-time. If we imagine space (-time) as a big blob of rubber in which we live, the curvature at a point describes how this blob is squeezed at that point. Since we live *inside* the rubber, we need to use 'insider' methods, such as excess radii and sectional curvatures, to describe the deformation. Relativity often seems difficult to learn because people do not like to think about the vacuum in this way, and even less to explain it in this way. (For a hundred years it was an article of faith for every physicist to say that the vacuum was empty.) Picturing vacuum as a substance can help us in many ways to understand general relativity.

Ref. 447

Curvature and motion in general relativity

As mentioned above, one half of general relativity is the statement that any object moves along paths of *maximum* proper time, i.e., along geodesics. The *other* half is contained in a single expression: for *every* observer, the sum of all three *proper* sectional *spatial*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

curvatures at a point is given by

$$K_{(12)} + K_{(23)} + K_{(31)} = \frac{8\pi G}{c^4} W^{(0)} \tag{325}$$

where $W^{(0)}$ is the *proper* energy density at the point. The lower indices indicate the mixed curvatures defined by the three orthogonal directions 1, 2 and 3. This is all of general relativity in one paragraph.

Challenge 871 e An equivalent expression is easily found using the excess radius defined above, by introducing the mass $M = VW^{(0)}/c^2$. For the surface area A of the volume V containing the mass, we get

$$r_{\text{excess}} = r - \sqrt{A/4\pi} = \frac{G}{3c^2} M \,. \tag{326}$$

In short, general relativity affirms that for every observer, *the excess radius of a small sphere is given by the mass inside the sphere.*[*]

Note that the above expression implies that the average space curvature at a point in empty space *vanishes*. As we will see shortly, this means that near a spherical mass the negative of the curvature *towards* the mass is equal to twice the curvature *around* the mass; the total sum is thus zero.

Curvature will also differ from point to point. In particular, the expression implies that if energy *moves*, curvature will move with it. In short, both space curvature and, as we will see shortly, space-time curvature *change* over space and time.

Challenge 872 ny We note in passing that curvature has an annoying effect: the relative velocity of *distant* observers is undefined. Can you provide the argument? In curved space, relative velocity is defined only for *nearby* objects – in fact only for objects at no distance at all. Only in flat space are relative velocities of distant objects well defined.

The quantities appearing in expression (325) are *independent* of the observer. But often people want to use observer-dependent quantities. The relation then gets more involved; the single equation (325) must be expanded to ten equations, called *Einstein's field equations*. They will be introduced below. But before we do that, we will check that general relativity makes sense. We will skip the check that it contains special relativity as a limiting case, and go directly to the main test.

Universal gravity

> The only reason which keeps me here is gravity.
> Anonymous

For small velocities and low curvature values, the temporal curvatures $K_{(0j)}$ turn out to have a special property. In this case, they can be defined as the second spatial derivatives Challenge 873 e of a single scalar function φ. In other words, we can write

Ref. 448 [*] Another, equivalent formulation is that for small radii the area A is given by

$$A = 4\pi r^2 (1 + \frac{1}{9} r^2 R) \tag{327}$$

where R is the Ricci scalar, to be introduced later on.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$K_{(0j)} = \frac{\partial^2 \varphi}{\partial (x^j)^2} \,. \tag{328}$$

In everyday situations, the function φ turns out to be the gravitational potential. Indeed, universal gravity is the limiting case of general relativity for small speeds and small spatial curvature. These two limits imply, making use of $W^{(0)} = \rho c^2$ and $c \to \infty$, that

$$K_{(ij)} = 0 \quad \text{and} \quad K_{(01)} + K_{(02)} + K_{(03)} = 4\pi G\rho \,. \tag{329}$$

In other words, for small speeds, space is flat and the potential obeys Poisson's equation. Universal gravity is thus indeed the low speed and low curvature limit of general relativity.

Challenge 874 ny Can you show that relation (325) between curvature and energy density indeed means that time near a mass depends on the height, as mentioned before?

The Schwarzschild metric

Ref. 446 What is the curvature of space-time near a spherical mass?

– CS – more to be inserted – CS –

Challenge 875 ny The curvature of the Schwarzschild metric is given by

$$\begin{aligned} K_{r\varphi} = K_{r\theta} &= -\frac{G}{c^2}\frac{M}{r^3} \quad \text{and} \quad K_{\theta\varphi} = 2\frac{G}{c^2}\frac{M}{r^3} \\ K_{t\varphi} = K_{t\theta} &= \frac{G}{c^2}\frac{M}{r^3} \quad \text{and} \quad K_{tr} = -2\frac{G}{c^2}\frac{M}{r^3} \end{aligned} \tag{330}$$

Ref. 446 Page 158 everywhere. The dependence on $1/r^3$ follows from the general dependence of all tidal effects; we have already calculated them in the chapter on universal gravity. The factors G/c^2 are due to the maximum force of gravity; only the numerical prefactors need to be calculated from general relativity. The average curvature obviously vanishes, as it does Challenge 876 ny for all vacuum. As expected, the values of the curvatures near the surface of the Earth are exceedingly small.

Curiosities and fun challenges about curvature

A fly has landed on the outside of a cylindrical glass, 1 cm below its rim. A drop of honey is located halfway around the glass, also on the outside, 2 cm below the rim. What is the Challenge 877 e shortest distance from the fly to the drop? What is the shortest distance if the drop is on the *inside* of the glass?

ALL OBSERVERS – HEAVIER MATHEMATICS

> Jeder Straßenjunge in unserem mathematischen Göttingen versteht mehr von vierdimensionaler Geometrie als Einstein. Aber trotzdem hat Einstein die Sache gemacht, und nicht die großen Mathematiker.
>
> David Hilbert*

Now that we have a feeling for curvature, we want to describe it in a way that allows *any* observer to talk to any *other* observer. Unfortunately, this means using formulae with tensors. These formulae look daunting. The challenge is to see in each of the expressions the essential point (e.g. by forgetting all indices for a while) and not to be distracted by those small letters sprinkled all over them.

The curvature of space-time

> Il faut suivre sa pente, surtout si elle monte.**
>
> André Gide

We mentioned above that a 4-dimensional space-time is described by 2-curvature, 3-curvature and 4-curvature. Many texts on general relativity start with 3-curvature. These curvatures describing the distinction between the 3-volume calculated from a radius and the actual 3-volume. They are described by the *Ricci tensor*.*** With an argument we encountered already for the case of geodesic deviation, it turns out that the Ricci tensor describes how the shape of a spherical cloud of freely falling particles is deformed on its path.

– CS – to be expanded – CS –

In short, the Ricci tensor is the general-relativistic version of $\Delta\varphi$, or better, of $\Box\varphi$.

The most global, but least detailed, definition of curvature is the one describing the distinction between the 4-volume calculated from a measured radius and the actual 4-volume. This is the *average curvature* at a space-time point and is represented by the so-called *Ricci scalar* R, defined as

$$R = -2K = -\frac{2}{r^2_{\text{curvature}}} \,. \tag{331}$$

It turns out that the Ricci scalar can be derived from the Ricci tensor by a so-called *contraction*, which is a precise averaging procedure. For tensors of rank two, contraction is

* 'Every street urchin in our mathematical Göttingen knows more about four-dimensional geometry than Einstein. Nevertheless, it was Einstein who did the work, not the great mathematicians.'

* This section might be skipped at first reading.

** 'One has to follow one's inclination, especially if it climbs upwards.'

*** Gregorio Ricci-Cubastro (b. 1853 Lugo , d. 1925 Bologna), Italian mathematician. He is the father of absolute differential calculus, once also called 'Ricci calculus'. Tullio Levi-Civita was his pupil.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the same as taking the trace:

$$R = R^{\lambda}{}_{\lambda} = g^{\lambda\mu} R_{\lambda\mu} \,. \tag{332}$$

The Ricci scalar describes the curvature averaged over space *and* time. In the image of a falling spherical cloud, the Ricci scalar describes the volume change of the cloud. The Ricci scalar always vanishes in vacuum. This result allows one, on the surface of the Earth, to relate the spatial curvature to the change of time with height.

Challenge 879 ny

Now comes an idea discovered by Einstein after two years of hard work. The important quantity for the description of curvature in nature is not the Ricci tensor R_{ab}, but a tensor built from it. This *Einstein tensor* G_{ab} is defined mathematically (for vanishing cosmological constant) as

$$G_{ab} = R_{ab} - \frac{1}{2} g_{ab} R \,. \tag{333}$$

It is not difficult to understand its meaning. The value G_{00} is the sum of sectional curvatures in the planes *orthogonal* to the 0 direction and thus the sum of all spatial sectional curvatures:

$$G_{00} = K_{(12)} + K_{(23)} + K_{(31)} \,. \tag{334}$$

Similarly, for each dimension i the diagonal element G_{ii} is the sum (taking into consideration the minus signs of the metric) of sectional curvatures in the planes *orthogonal* to the i direction. For example, we have

$$G_{11} = K_{(02)} + K_{(03)} - K_{(23)} \,. \tag{335}$$

The distinction between the Ricci tensor and the Einstein tensor thus lies in the way in which the sectional curvatures are combined: discs *containing* the coordinate in question in one case, discs *orthogonal* to the coordinate in the other case. Both describe the curvature of space-time equally well, and fixing one means fixing the other. (What are the trace and the determinant of the Einstein tensor?)

Challenge 880 d

The Einstein tensor is symmetric, which means that it has *ten* independent components. Most importantly, its divergence vanishes; it therefore describes a conserved quantity. This was the essential property which allowed Einstein to relate it to mass and energy in mathematical language.

The description of momentum, mass and energy

Obviously, for a complete description of gravity, also motions of momentum and energy also need to be quantified in such a way that any observer can talk to any other. We have seen that momentum and energy always appear together in relativistic descriptions; the next step is thus to find out how their motions can be quantified for general observers.

First of all, the quantity describing energy, let us call it T, must be defined using the energy–momentum vector $\boldsymbol{p} = m\boldsymbol{u} = (\gamma mc, \gamma m\boldsymbol{v})$ of special relativity. Furthermore, T does not describe a single particle, but the way energy–momentum is distributed over space and time. As a consequence, it is most practical to use T to describe a *density* of energy and momentum. T will thus be a *field*, and depend on time and space, a fact

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

usually indicated by the notation $T = T(t, x)$.

Since the energy–momentum density T describes a density over space and time, it defines, at every space-time point and for every infinitesimal surface $\mathrm{d}\boldsymbol{A}$ around that point, the flow of energy–momentum $\mathrm{d}\boldsymbol{p}$ through that surface. In other words, T is defined by the relation

$$\mathrm{d}\boldsymbol{p} = T\,\mathrm{d}\boldsymbol{A}\,. \tag{336}$$

The surface is assumed to be characterized by its normal vector $\mathrm{d}\boldsymbol{A}$. Since the energy–momentum density is a proportionality factor between two vectors, T is a *tensor*. Of course, we are talking about 4-flows and 4-surfaces here. Therefore the energy–momentum density tensor can be split in the following way:

$$T = \left(\begin{array}{c|ccc} w & S_1 & S_2 & S_3 \\ \hline S_1 & t_{11} & t_{12} & t_{13} \\ S_2 & t_{21} & t_{22} & t_{23} \\ S_3 & t_{31} & t_{32} & t_{33} \end{array}\right) = \left(\begin{array}{c|c} \text{energy density} & \text{energy flow or momentum density} \\ \hline \text{energy flow or momentum density} & \text{momentum flow density} \end{array}\right) \tag{337}$$

where $w = T_{00}$ is a 3-scalar, $\boldsymbol{S}$ a 3-vector and t a 3-tensor. The total quantity T is called the *energy–momentum* (*density*) *tensor*. It has two essential properties: it is symmetric and its divergence vanishes.

The vanishing divergence of the tensor T, often written as

$$\partial_a T^{ab} = 0 \quad \text{or abbreviated} \quad T^{ab}{}_{,a} = 0\,, \tag{338}$$

expresses the fact that the tensor describes a *conserved* quantity. In every volume, energy can change only via flow through its boundary surface. Can you confirm that the description of energy–momentum with this tensor satisfies the requirement that any two observers, differing in position, orientation, speed *and* acceleration, can communicate their results to each other?

Challenge 881 ny

The energy–momentum density tensor gives a full description of the distribution of energy, momentum and mass over space and time. As an example, let us determine the energy–momentum density for a moving liquid. For a liquid of density ρ, a pressure p and a 4-velocity $\boldsymbol{u}$, we have

$$T^{ab} = (\rho_0 + p)u^a u^b - p g^{ab} \tag{339}$$

where ρ_0 is the density measured in the comoving frame, the so-called *proper* density.* Obviously, ρ, ρ_0 and p depend on space and time.

* In the *comoving* frame we thus have

$$T^{ab} = \begin{pmatrix} \rho_0 c^2 & 0 & 0 & 0 \\ 0 & p & 0 & 0 \\ 0 & 0 & p & 0 \\ 0 & 0 & 0 & p \end{pmatrix}. \tag{340}$$

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Of course, for a particular material fluid, we need to know how pressure p and density ρ are related. A full material characterization thus requires the knowledge of the relation

$$p = p(\rho) \,. \tag{341}$$

This relation is a material property and thus *cannot* be determined from relativity. It has to be derived from the constituents of matter or radiation and their interactions. The simplest possible case is *dust*, i.e., matter made of point particles* with no interactions at all. Its energy–momentum tensor is given by

$$T^{ab} = \rho_0 u^a u^b \,. \tag{342}$$

Challenge 882 ny Can you explain the difference from the liquid case?

The divergence of the energy–momentum tensor vanishes for all times and positions, Challenge 883 ny as you may want to check. This property is the same as for the Einstein tensor presented above. But before we elaborate on this issue, a short remark. We did not take into account *gravitational energy*. It turns out that gravitational energy cannot be defined in general. Gravity is *not* an interaction and does *not* have an associated energy.**

Hilbert's action – how things fall?

When Einstein discussed his work with David Hilbert, Hilbert found a way to do in a few weeks what had taken years for Einstein. Hilbert understood that general relativity *in empty space* could be described by an action integral, like all other physical systems.

Thus Hilbert set out to find the measure of change, as this is what an action describes, for motion due to gravity. Obviously, the measure must be observer-invariant; in particular, it must be invariant under all possible changes of viewpoints.

Motion due to gravity is determined by curvature. Any curvature measure independent of the observer must be a combination of the Ricci scalar R and the cosmological constant Λ. It thus makes sense to expect that the change of space-time is described by an action S given by

$$S = \frac{c^4}{16\pi G} \int (R + 2\Lambda) \, \mathrm{d}V \,. \tag{343}$$

The volume element $\mathrm{d}V$ must be specified to use this expression in calculations. The cosmological constant Λ (added some years after Hilbert's work) appears as a mathematical possibility to describe the most general action that is diffeomorphism-invariant. We will see below that its value in nature, though small, seems to be different from zero.

The Hilbert action of a chunk of space-time is thus the integral of the Ricci scalar plus

* Even though general relativity expressly forbids the existence of point particles, the approximation is useful in cases when the particle distances are large compared to their own size.

** In certain special circumstances, such as weak fields, slow motion, or an asymptotically flat space-time, we *can* define the integral of the G^{00} component of the Einstein tensor as negative gravitational energy. Gravitational energy is thus only defined *approximately*, and only for our everyday environment. Nevertheless, this approximation leads to the famous speculation that the total energy of the universe is zero. Do you agree? Page 598 Challenge 884 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

twice the cosmological constant over that chunk. The principle of least action states that space-time moves in such a way that this integral changes as little as possible.

– CS – to be finished – CS –

In summary, the question 'how do things move?' is answered by general relativity in the same way as by special relativity: *things follow the path of maximal ageing*.

Challenge 885 ny Can you show that the Hilbert action follows from the maximum force?

The symmetries of general relativity

The main symmetry of the Lagrangian of general relativity is called *diffeomorphism invariance*.

– CS – to be written – CS –

The field equations for empty space-time also show *scale symmetry*. This is the invariance of the equations after multiplication of all coordinates by a common numerical factor. In 1993, Torre and Anderson showed that diffeomorphism symmetry and trivial

Ref. 449 scale symmetry are the *only* symmetries of the vacuum field equations.

Apart from diffeomorphism symmetry, full general relativity, including mass–energy, has an additional symmetry which is not yet fully elucidated. This symmetry connects the various possible initial conditions of the field equations; the symmetry is extremely

Ref. 450 complex and is still a topic of research. These fascinating investigations should give new insights into the classical description of the big bang.

Einstein's field equations

> [Einstein's general theory of relativity] cloaked the ghastly appearance of atheism.
>
> A witch hunter from Boston, around 1935

> Do you believe in god? Prepaid reply 50 words.
>
> Subsequent telegram by another to his hero Albert Einstein

> I believe in Spinoza's god, who reveals himself in the orderly harmony of what exists, not in a god who concerns himself with fates and actions of human beings.
>
> Albert Einstein's answer

Einstein's famous field equations were the basis of many religious worries. They contain

Page 476 the full description of general relativity. As explained above, they follow from the maxi-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

mum force – or equivalently, from Hilbert's action – and are given by

$$G_{ab} = -\kappa\, T_{ab}$$

or

$$R_{ab} - \frac{1}{2} g_{ab} R - \Lambda g_{ab} = -\kappa\, T^{ab} \,. \tag{344}$$

The constant κ, called the *gravitational coupling constant*, has been measured to be

$$\kappa = \frac{8\pi G}{c^4} = 2.1 \cdot 10^{-43}\,/\mathrm{N} \tag{345}$$

and its small value – 2π divided by the maximum force $c^4/4G$ – reflects the weakness of gravity in everyday life, or better, the difficulty of bending space-time. The constant Λ, the so-called *cosmological constant*, corresponds to a vacuum energy volume density, or pressure Λ/κ. Its low value is quite hard to measure. The currently favoured value is

Page 587

$$\Lambda \approx 10^{-52}\,/\mathrm{m}^2 \quad \text{or} \quad \Lambda/\kappa \approx 0.5\,\mathrm{nJ/m^3} = 0.5\,\mathrm{nPa} \,. \tag{346}$$

Ref. 451 Current measurements and simulations suggest that this parameter, even though it is numerically near to the inverse square of the present radius of the universe, is a constant of nature that does not vary with time.

In summary, the field equations state that the curvature at a point is equal to the flow of energy–momentum through that point, taking into account the vacuum energy density. In other words, *energy–momentum tells space-time how to curve.**

The field equations of general relativity can be simplified for the case in which speeds are small. In that case $T_{00} = \rho c^2$ and all other components of T vanish. Using the defini-

* Einstein arrived at his field equations using a number of intellectual guidelines that are called *principles* in the literature. Today, many of them are not seen as central any more. Nevertheless, we give a short overview.

- *Principle of general relativity*: all observers are equivalent; this principle, even though often stated, is probably empty of any physical content.

- *Principle of general covariance*: the equations of physics must be stated in tensorial form; even though Ref. 452 it is known today that all equations can be written with tensors, even universal gravity, in many cases they require unphysical 'absolute' elements, i.e., quantities which affect others but are not affected themselves. Page 855 This unphysical idea is in contrast with the idea of *inter*action, as explained above.

- *Principle of minimal coupling*: the field equations of gravity are found from those of special relativity by taking the simplest possible generalization. Of course, now that the equations are known and tested experimentally, this principle is only of historical interest.

- *Equivalence principle*: acceleration is locally indistinguishable from gravitation; we used it to argue that space-time is semi-Riemannian, and that gravity is its curvature.

- *Mach's principle*: inertia is due to the interaction with the rest of the universe; this principle is correct, even though it is often maintained that it is not fulfilled in general relativity. In any case, it is not the essence Page 601 of general relativity.

- *Identity of gravitational and inertial mass*: this is included in the definition of mass from the outset, but restated ad nauseam in general relativity texts; it is implicitly used in the definition of the Riemann tensor.

- *Correspondence principle*: a new, more general theory, such as general relativity, must reduce to previous theories, in this case universal gravity or special relativity, when restricted to the domains in which those are valid.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 886 ny

tion of the constant κ and setting $\varphi = (c^2/2)h_{00}$ in $g_{ab} = \eta_{ab} + h_{ab}$, we find

$$\nabla^2\varphi = 4\pi\rho \quad \text{and} \quad \frac{\mathrm{d}^2x}{\mathrm{d}t^2} = -\nabla\varphi \tag{347}$$

which we know well, since it can be restated as follows: a body of mass m near a body of mass M is accelerated by

$$a = G\frac{M}{r^2}, \tag{348}$$

a value which is independent of the mass m of the falling body. And indeed, as noted already by Galileo, all bodies fall with the same acceleration, independently of their size, their mass, their colour, etc. In general relativity also, gravitation is completely democratic.* The independence of free fall from the mass of the falling body follows from the description of space-time as a bent mattress. Objects moving on a mattress also move in the same way, independently of the mass value.

To get a feeling for the complete field equations, we will take a short walk through their main properties. First of all, all motion due to space-time curvature is *reversible*,

Challenge 887 e

differentiable and thus *deterministic*. Note that only the complete motion, of space-time *and* matter *and* energy, has these properties. For particle motion only, motion is in fact *irreversible*, since some gravitational radiation is usually emitted.

By contracting the field equations we find, for vanishing cosmological constant, the following expression for the Ricci scalar:

$$R = -\kappa T\,. \tag{353}$$

This result also implies the relation between the excess radius and the mass inside a

Challenge 888 ny

sphere.

The field equations are *nonlinear* in the metric g, meaning that sums of solutions usually are *not* solutions. That makes the search for solutions rather difficult. For a complete solution of the field equations, initial and boundary conditions should be specified. The

Ref. 453

ways to do this form a specialized part of mathematical physics; it is not explored here.

* Here is another way to show that general relativity fits with universal gravity. From the definition of the Riemann tensor we know that relative acceleration b_a and speed of nearby particles are related by

$$\nabla_e b_a = R_{ceda}v^c v^d\,. \tag{349}$$

From the symmetries of R we know there is a φ such that $b_a = -\nabla_a\varphi$. That means that

$$\nabla_e b^a = \nabla_e\nabla^a\varphi = R^a_{ced}v^c v^d \tag{350}$$

which implies that

$$\Delta\varphi = \nabla_a\nabla^a\varphi = R^a_{cad}v^c v^d = R_{cd}v^c v^d = \kappa(T_{cd}v^c v^d - T/2) \tag{351}$$

Introducing $T_{ab} = \rho v_a v_b$ we get

$$\Delta\varphi = 4\pi G\rho \tag{352}$$

as we wanted to show.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Albert Einstein used to say that general relativity only provides the understanding of one side of the field equations (344), but not of the other. Can you see which side he meant?

Challenge 889 ny

What can we do of interest with these equations? In fact, to be honest, not much that we have not done already. Very few processes require the use of the full equations. Many textbooks on relativity even stop after writing them down! However, studying them is worthwhile. For example, one can show that the Schwarzschild solution is the *only* spherically symmetric solution. Similarly, in 1923, Birkhoff showed that every rotationally symmetric vacuum solution is static. This is the case even if masses themselves move, as for example during the collapse of a star.

Maybe the most beautiful applications of the field equations are the various *films* made of relativistic processes. The worldwide web hosts several of these; they allow one to see what happens when two black holes collide, what happens when an observer falls into a black hole, etc. To generate these films, the field equations usually need to be solved directly, without approximations.*

– CS – more to be added – CS –

Another area of application concerns *gravitational waves*. The full field equations show that waves are not harmonic, but nonlinear. Sine waves exist only approximately, for small amplitudes. Even more interestingly, if two waves collide, in many cases *singularities* are predicted to appear. This whole theme is still a research topic and might provide new insights for the quantization of general relativity in the coming years.

We end this section with a side note. Usually, the field equations are read in one sense only, as stating that energy–momentum produces curvature. One can also read them in the other way, calculating the energy–momentum needed to produces a given curvature. When one does this, one discovers that not all curved space-times are possible, as some would lead to *negative* energy (or mass) densities. Such solutions would contradict the mentioned limit on length-to-mass ratios for physical systems.

More on the force limit

When the cosmological constant is taken into the picture, the maximum force principle requires a second look. In the case of a non-vanishing cosmological constant, the force limit makes sense only if the constant Λ is positive; this is the case for the currently measured value, which is $\Lambda \approx 10^{-52}/\mathrm{m}^2$. Indeed, the radius–mass relation of black holes

Ref. 454

Ref. 392, Ref. 393

$$2GM = Rc^2\left(1 - \frac{\Lambda}{3}R^2\right) \tag{354}$$

implies that a radius-*independent* maximum force is valid only for positive or zero cosmological constant. For a negative cosmological constant the force limit would only be valid for infinitely small black holes. In the following, we take a pragmatic approach and note that a maximum force limit can be seen to imply a vanishing or positive cosmological constant. Obviously, the force limit does not specify the *value* of the constant; to

* See for example the www.photon.at/~werner/black-earth website.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

achieve this, a second principle needs to be added. A straightforward formulation, using
Page 496 the additional principle of a minimum force in nature, was proposed above.

One might ask also whether rotating or charged black holes change the argument that leads from maximum force to the derivation of general relativity. However, the derivation using the Raychaudhuri equation does not change. In fact, the only change of the argument appears with the inclusion of torsion, which changes the Raychaudhuri equation itself. As long as torsion plays no role, the derivation given above remains valid. The inclusion of torsion is still an open research issue.

Another question is how maximum force relates to scalar–tensor theories of gravity, such as the proposal by Brans and Dicke or its generalizations. If a particular scalar-tensor theory obeys the general horizon equation (244) then it must also imply a maximum force. The general horizon equation must be obeyed both for *static* and for *dynamic* horizons. If that were the case, the specific scalar–tensor theory would be equivalent to general relativity, as it would allow one, using the argument of Jacobson, to deduce the usual field equations. This case can appear if the scalar field behaves like matter, i.e., if it has mass–energy like matter and curves space-time like matter. On the other hand, if in the particular scalar–tensor theory the general horizon equation (244) is not obeyed for *all moving* horizons – which is the general case, as scalar–tensor theories have more defining constants than general relativity – then the maximum force does not appear and the theory is not equivalent to general relativity. This connection also shows that an experimental test of the horizon equation for *static* horizons only is not sufficient to confirm general relativity; such a test rules out only some, but not all, scalar–tensor theories.

Deducing universal gravity

For the maximum force limit to be considered a basic physical principle, all properties of gravitation, including the full theory of general relativity, must be deduced from it. To make this argument easier to follow, we will split it into several steps. First of all, we show that the force limit implies that in everyday life the inverse square law of universal gravity holds. Then we show that it implies the main ideas of general relativity. Finally, we show that the full theory of general relativity follows.

In other words, from this point onwards the force limit is assumed to be valid. We explore its consequences and compare them with the known properties of nature. The maximum force limit can also be visualized in another way. If the gravitational attraction between a central body and a satellite were *stronger* than it is, black holes would be smaller than they are; in that case the maximum force limit and the maximum speed could be exceeded. If, on the other hand, gravitation were *weaker* than it is, a fast and accelerating observer would not be able to determine that the two bodies interact. In summary, a maximum force of $c^4/4G$ implies universal gravity. There is no difference between stating that all bodies attract through gravitation and stating that there is a maximum force with the value $c^4/4G$.

Deducing linearized general relativity

The next logical step is to show that a maximum force also implies general relativity. The naive approach is to repeat, step by step, the standard approach to general relativity.

Space-time curvature is a consequence of the fact that the speed of light is the maxi-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 392, Ref. 393 mum speed for *all* observers, even if they are located in a gravitational field. The gravitational red shift shows that in gravitational fields, clocks change their rate with height; that change, together with the constancy of the speed of light, implies space-time curvature. Gravity thus implies space-time curvature. The value of the curvature in the case of weak gravitational fields is completely fixed by the inverse square law of gravity. Since universal gravity follows from the maximum force, we deduce that maximum force implies space-time curvature.

Apart from curvature, we must also check the other basic ideas of general relativity. The *principle of general relativity* states that all observers are equivalent; since the maximum force principle applies to all observers, the principle of general relativity is contained in it. The *equivalence principle* states that, locally, gravitation can be transformed away by changing to a suitable observer. This is also the case for the maximum force principle, which is claimed for all observers, thus also for observers that locally eliminate gravitation. *Mach's principle*, whose precise formulation varies, states that only relative quantities should play a role in the description of nature. Since the maximum force is a relative quantity – in particular, the relation of mass and curvature remains – Mach's principle is also satisfied.

Free bodies in flat space move with constant speed. By the equivalence principle, this statement generalizes to the statement that freely falling bodies move along geodesics. The maximum force principle keeps intact the statement that *space-time tells matter how to move*.

The curvature of space-time for weak gravitational fields is fixed by the inverse square law of gravity. Space curvature is thus present in the right amount around each mass.
Ref. 455 As Richard Feynman explains, by extending this result to all possible observers, we can deduce all low-curvature effects of gravitation. In particular, this implies the existence of linear (low-amplitude) gravitational waves and of the Thirring–Lense effect. Linearized general relativity thus follows from the maximum force principle.

How to calculate the shape of geodesics

The other half of general relativity states that bodies fall along geodesics. All orbits are geodesics, thus curves with the longest proper time. It is thus useful to be able to calculate these trajectories.* To start, one needs to know the *shape of space-time*, the notion of 'shape' being generalized from its familiar two-dimensional meaning. For a being living on the surface, it is usually described by the metric g_{ab}, which defines the distances between neighbouring points through

$$\mathrm{d}s^2 = \mathrm{d}x_a \, \mathrm{d}x^a = g_{ab}(x) \, \mathrm{d}x^a \, \mathrm{d}x^b \,. \tag{355}$$

It is a famous exercise of calculus to show from this expression that a curve $x^a(s)$ depending on a well behaved (affine) parameter s is a timelike or spacelike (metric) *geodesic*, i.e.,
Challenge 890 ny the longest possible path between the two events,** only if

* This is a short section for the more curious; it can be skipped at first reading.

** We remember that in space in everyday life, geodesics are the shortest possible paths; however, in space-time in general relativity, geodesics are the longest possible paths. In both cases, they are the 'straightest' possible paths.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

$$\frac{\mathrm{d}}{\mathrm{d}s}\left(g_{ad}\frac{\mathrm{d}x^d}{\mathrm{d}s}\right) = \frac{1}{2}\frac{\partial g_{bc}}{\partial x^a}\frac{\mathrm{d}x^b}{\mathrm{d}s}\frac{\mathrm{d}x^c}{\mathrm{d}s}\,, \tag{356}$$

as long as ds is different from zero along the path.* All bodies in free fall follow such geodesics. We showed above that the geodesic property implies that a stone thrown in the air falls back, unless if it is thrown with a speed larger than the escape velocity. Expression (356) thus replaces both the expression $\mathrm{d}^2x/\mathrm{d}t^2 = -\nabla\varphi$ valid for falling bodies and the expression $\mathrm{d}^2x/\mathrm{d}t^2 = 0$ valid for freely floating bodies in special relativity.

Page 510

The path does not depend on the mass or on the material of the body. Therefore *antimatter* also falls along geodesics. In other words, antimatter and matter do not repel; they also attract each other. Interestingly, even experiments performed with normal matter can show this, if they are carefully evaluated. Can you find out how?

Ref. 456

Challenge 891 ny

For completeness, we mention that light follows *lightlike* or *null* geodesics. In other words, there is an affine parameter u such that the geodesics follow

$$\frac{\mathrm{d}^2x^a}{\mathrm{d}u^2} + \Gamma^a{}_{bc}\frac{\mathrm{d}x^b}{\mathrm{d}u}\frac{\mathrm{d}x^c}{\mathrm{d}u} = 0 \tag{360}$$

with the different condition

$$g_{ab}\frac{\mathrm{d}x^a}{\mathrm{d}u}\frac{\mathrm{d}x^b}{\mathrm{d}u} = 0\,. \tag{361}$$

Given all these definitions of various types of geodesics, what are the lines drawn in Figure 274 on page 505?

Challenge 892 ny

Mass in general relativity

The diffeomorphism-invariance of general relativity makes life quite interesting. We will see that it allows us to say that we live on the *inside* of a hollow sphere, and that it does not allow us to say where energy is actually located. If energy cannot be located, what about mass? It soon becomes clear that mass, like energy, can be localized *only* if distant space-time is known to be flat. It is then possible to define a localized mass value by making precise an intuitive idea: the mass is measured by the time a probe takes to orbit

* This is often written as

$$\frac{\mathrm{d}^2x^a}{\mathrm{d}s^2} + \Gamma^a_{bc}\frac{\mathrm{d}x^b}{\mathrm{d}s}\frac{\mathrm{d}x^c}{\mathrm{d}s} = 0 \tag{357}$$

where the condition

$$g_{ab}\frac{\mathrm{d}x^a}{\mathrm{d}s}\frac{\mathrm{d}x^b}{\mathrm{d}s} = 1 \tag{358}$$

must be fulfilled, thus simply requiring that all the tangent vectors are *unit* vectors, and that d$s \neq 0$ all along the path. The symbols Γ appearing above are given by

$$\Gamma^a{}_{bc} = \left\{ {a \atop bc} \right\} = \frac{1}{2}g^{ad}\left(\partial_b g_{dc} + \partial_c g_{db} - \partial_d g_{bc}\right)\,, \tag{359}$$

and are called *Christoffel symbols of the second kind* or simply the *metric connection*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the unknown body.*

The intuitive mass definition *requires* flat space-time at infinity; it cannot be extended to other situations. In short, mass can only be localized if total mass can be defined. And *total mass* is defined only for asymptotically flat space-time. The only other notion of mass that is precise in general relativity is the *local mass density* at a point. In contrast, it is not well understood how to define the mass contained in a region larger than a point but smaller than the entirety of space-time.

Challenge 893 ny

Now that we can go on talking about mass without (too much of) a bad conscience, we turn to the equations of motion.

Is gravity an interaction?

We tend to answer this question affirmatively, as in Galilean physics gravity was seen as an influence on the motion of bodies. In fact, we described it by a potential, implying that gravity *produces* motion. But let us be careful. A force or an interaction is what changes the motion of objects. However, we just saw that when two bodies attract each other through gravitation, both always remain in free fall. For example, the Moon circles the Earth because it continuously falls around it. Since any freely falling observer continuously remains at rest, the statement that gravity changes the motion of bodies is not correct for all observers. Indeed, we will soon discover that in a sense to be discussed shortly, the Moon and the Earth both follow 'straight' paths.

Is this correction of our idea of gravity only a question of words? Not at all. Since gravity is not an interaction, it is *not* due to a field and there is *no* potential.

Page 855

Let us check this strange result in yet another way. The most fundamental definition of 'interaction' is as the difference between the whole and the sum of its parts. In the case of gravity, an observer in free fall could claim that nothing special is going on, independently of whether the other body is present or not, and could claim that gravity is not an interaction.

However, that is going too far. An interaction transports energy between systems. We have indeed seen that gravity can be said to transport energy only approximately. Gravitation is thus an interaction only approximately. But that is not a sufficient reason to abandon this characterization. The concept of energy is not useful for gravity beyond the domain of everyday life. For the general case, namely for a general observer, gravity is thus fundamentally different from electricity or magnetism.

Another way to look at the issue is the following. Take a satellite orbiting Jupiter with energy–momentum $\boldsymbol{p} = m\boldsymbol{u}$. If we calculate the energy–momentum change along its

* This definition was formalized by Arnowitt, Deser and Misner, and since then has often been called the *ADM mass*. The idea is to use the metric g_{ij} and to take the integral

$$m = \frac{1}{16\pi} \int_{S_R} (g_{ij,i} v_j - g_{ii,j} v_j) \mathrm{d}A \tag{362}$$

where S_R is the coordinate sphere of radius R, v is the unit vector normal to the sphere and $\mathrm{d}A$ is the area element on the sphere. The limit exists if space-time is asymptotically flat and if the mass distribution is sufficiently concentrated. Mathematical physicists have also shown that for any manifold whose metric changes at infinity as

Ref. 457

$$g_{ij} = (1 + f/r + O(1/r^2))\delta_{ij} \tag{363}$$

the total mass is given by $M = 2f$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 894 ny path s, we get

$$\frac{\mathrm{d}\boldsymbol{p}}{\mathrm{d}s} = m\frac{\mathrm{d}\boldsymbol{u}}{\mathrm{d}s} = m(\boldsymbol{e}_a\frac{\mathrm{d}\boldsymbol{u}^a}{\mathrm{d}s} + \frac{\mathrm{d}\boldsymbol{e}_a}{\mathrm{d}s}\boldsymbol{u}^a) = m\boldsymbol{e}_a(\frac{\mathrm{d}\boldsymbol{u}^a}{\mathrm{d}s} + \Gamma^a{}_{bd}\boldsymbol{u}^b\boldsymbol{u}^c) = 0 \qquad (364)$$

where $\boldsymbol{e}$ describes the unit vector along a coordinate axis. The energy–momentum Challenge 895 ny change vanishes along any geodesic, as you might check. Therefore, the energy–momentum of this motion is conserved. In other words, *no* force is acting on the satellite. One could reply that in equation (364) the second term alone is the gravitational force. But this term can be made to vanish along the entirety of any given world Ref. 458 line. In short, nothing changes between two bodies in free fall around each other: gravity Challenge 896 ny could be said not to be an interaction. The properties of energy confirm this argument. Challenge 897 s

Of course, the conclusion that gravity is not an interaction is somewhat academic, as it contradicts our experience of daily life. But we will need it for the full understanding of motion later on. The behaviour of radiation confirms the deduction. In vacuum, radiation is always moving freely. In a sense, we can say that radiation always is in free fall. Strangely, since we called free fall the same as rest, we should conclude that radiation always is at rest. This is not wrong! We have already seen that light cannot be accelerated.* We even saw that gravitational bending is not an acceleration, since light follows straight paths in space-time in this case as well. Even though light seems to slow down near masses for distant observers, it always moves at the speed of light locally. In short, even gravitation doesn't manage to move light.

There is another way to show that light is always at rest. A clock for an observer trying to reach the speed of light goes slower and slower. For light, in a sense, time stops: or, if you prefer, *light does not move*.

The essence of general relativity

If a maximum power or force appearing on horizons is the basis for general relativity, one can ask whether physical systems other than space-time can also be described in this way.

For special relativity, we found that all its main effects – such as a limit speed, Lorentz contraction or energy–mass equivalence – are also found for dislocations in solids. Do systems analogous to general relativity exist? Attempts to find such systems have only been partially successful. Several equations and ideas of general relativity are applicable to deformations of solids, since general relativity describes the deformation of the Ref. 459 space-time mattress. Kröner has studied this analogy in great detail. Other systems with horizons, and thus with observables analogous to curvature, are found in certain liquids – where vortices play the role of black holes – and in certain quantum fluids for the propRef. 460 agation of light. Exploring such systems has become a research topic in its own right. A full analogy of general relativity in a macroscopic system was discovered only a few

* Refraction, the slowdown of light inside matter, is not a counter-example. Strictly speaking, light inside matter is constantly being absorbed and re-emitted. In between these processes, light still propagates with the speed of light in vacuum. The whole process only *looks* like a slowdown in the macroscopic limit. The same applies to diffraction and to reflection. A list of apparent ways to bend light can be found on page 737; details of the quantum-mechanical processes at their basis can be found on page 1006.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

years ago. This analogy will be presented in the final part of our adventure; we will need an additional ingredient that is not visible at this point of our ascent.

Riemann gymnastics

Most books introduce curvature the hard way, namely historically,* using the Riemann curvature tensor. This is a short summary, so that you can understand that old stuff when you come across it.

We saw above that curvature is best described by a tensor. In 4 dimensions, this curvature tensor, usually called R, must be a quantity which allows us to calculate, among other things, the area for any orientation of a 2-disc in space-time. Now, in 4 dimensions, orientations of a disc are defined in terms of *two* 4-vectors; let us call them $\boldsymbol{p}$ and $\boldsymbol{q}$. And instead of a disc, we take the *parallelogram* spanned by $\boldsymbol{p}$ and $\boldsymbol{q}$. There are several possible definitions.

Challenge 898 e

The *Riemann-Christoffel curvature tensor* R is then defined as a quantity which allows us to calculate the curvature $K(\boldsymbol{p}, \boldsymbol{q})$ for the surface spanned by $\boldsymbol{p}$ and $\boldsymbol{q}$, with area A, through

$$K(\boldsymbol{p}, \boldsymbol{q}) = \frac{R\, \boldsymbol{pqpq}}{A^2(\boldsymbol{p}, \boldsymbol{q})} = \frac{R_{abcd} p^a q^b p^c q^d}{(g_{\alpha\delta} g_{\beta\gamma} - g_{\alpha\gamma} g_{\beta\delta}) p^\alpha q^\beta p^\gamma q^\delta} \tag{365}$$

where, as usual, Latin indices a, b, c, d, etc. run from 0 to 3, as do Greek indices here, and a *summation* is implied when an index name appears twice. Obviously R is a tensor, of rank 4. This tensor thus describes only the *intrinsic* curvature of a space-time. In contrast, the metric g describes the complete *shape* of the surface, not only the curvature. The curvature is thus the physical quantity of relevance locally, and physical descriptions therefore use only the *Riemann*** *tensor* R or quantities derived from it.***

But we can forget the just-mentioned definition of curvature. There is a second, more physical way to look at the Riemann tensor. We know that curvature means gravity. As we said above, gravity means that when two nearby particles move freely with the same velocity and the same direction, the distance between them changes. In other words, the

Challenge 899 e

* This is a short section for the more curious; it can be skipped at first reading.

** Bernhard Riemann (b. 1826 Breselenz, d. 1866 Selasca), important German mathematician. One among his numerous important achievements is the foundation of non-Euclidean geometry.

*** We showed above that space-time is curved by noting changes in clock rates, in metre bar lengths and in light propagation. Such experiments are the easiest way to determine the metric g. We know that space-time is described by a 4-dimensional manifold M with a metric g_{ab} that locally, at each space-time point, is a Minkowski metric. Such a manifold is called a *Riemannian manifold*. Only such a metric allows one to define a local inertial system, i.e., a local Minkowski space-time at every space-time point. In particular, we have

$$g_{ab} = 1/g^{ab} \quad \text{and} \quad g_a{}^b = g^a{}_b = \delta^a_b \,. \tag{366}$$

How are curvature and metric related? The solution to this question usually occupies a large number of pages in relativity books; just for information, the relation is

$$R^a{}_{bcd} = \frac{\partial \Gamma^a{}_{bd}}{\partial x^c} - \frac{\partial \Gamma^a{}_{bc}}{\partial x^d} + \Gamma^a{}_{ec} \Gamma^e{}_{bd} - \Gamma^a{}_{fd} \Gamma^f{}_{bc} \,. \tag{367}$$

The curvature tensor is built from the second derivatives of the metric. On the other hand, we can also determine the metric if the curvature is known. An approximate relation is given below.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

local effect of gravity is *relative acceleration* of nearby particles.

It turns out that the tensor R describes precisely this relative acceleration, i.e., what we called the *tidal effects* earlier on. Obviously, the relative acceleration $\boldsymbol{b}$ increases with the separation $\boldsymbol{d}$ and the square (why?) of the speed $\boldsymbol{u}$ of the two particles. Therefore we can also define R as a (generalized) proportionality factor among these quantities:

Challenge 900 ny

$$\boldsymbol{b} = R\,\boldsymbol{u}\,\boldsymbol{u}\,\boldsymbol{d} \quad \text{or, more clearly,} \quad b^a = R^a{}_{bcd}\, u^b\, u^c\, d^d \,. \tag{368}$$

The components of the Riemann curvature tensor have the dimensions of inverse square length. Since it contains all information about intrinsic curvature, we conclude that if R vanishes in a region, space-time in that region is flat. This connection is easily deduced from this second definition.*

Challenge 901 ny

A final way to define the tensor R is the following. For a *free-falling* observer, the metric g_{ab} is given by the metric η_{ab} from special relativity. In its neighbourhood, we have

$$\begin{aligned} g_{ab} &= \eta_{ab} + \frac{1}{3} R_{acbd} x^c x^d + O(x^3) \\ &= \frac{1}{2} (\partial_c \partial_d g_{ab}) x^c x^d + O(x^3) \,. \end{aligned} \tag{370}$$

The curvature term thus describes the departure of the space-time metric from that of flat space-time. The curvature tensor R is a large beast; it has $4^4 = 256$ components at each point of space-time; however, its symmetry properties reduce them to 20 independent numbers.** The actual number of importance in physical problems is still smaller, namely only 10. These are the components of the Ricci tensor, which can be defined with

---

* This second definition is also called the definition through *geodesic deviation*. It is of course not evident that it coincides with the first. For an explicit proof, see the literature. There is also a third way to picture the tensor R, a more mathematical one, namely the original way Riemann introduced it. If one parallel-transports a vector $\boldsymbol{w}$ around a parallelogram formed by two vectors $\boldsymbol{u}$ and $\boldsymbol{v}$, each of length ε, the vector $\boldsymbol{w}$ is changed to $\boldsymbol{w} + \delta\boldsymbol{w}$. One then has

Ref. 461

$$\delta\boldsymbol{w} = -\varepsilon^2 R\,\boldsymbol{u}\,\boldsymbol{v}\,\boldsymbol{w} + \quad \text{higher-order terms} \quad . \tag{369}$$

More can be learned about the geodesic deviation by studying the behaviour of the famous south-pointing carriage which we have encountered before. This device, common in China before the compass was discovered, only works if the world is flat. Indeed, on a curved surface, after following a large closed path, it will show a different direction than at the start of the trip. Can you explain why?

Page 191

Challenge 902 ny

** The free-fall definition shows that the Riemann tensor is symmetric in certain indices and antisymmetric in others:

Challenge 903 ny

$$R_{abcd} = R_{cdab} \quad , \quad R_{abcd} = -R_{bacd} = -R_{abdc} \,. \tag{371}$$

These relations also imply that many components vanish. Of importance also is the relation

$$R_{abcd} + R_{adbc} + R_{acdb} = 0 \,. \tag{372}$$

Note that the order of the indices is not standardized in the literature. The list of invariants which can be constructed from R is long. We mention that $\frac{1}{2}\varepsilon^{abcd} R_{cd}{}^{ef} R_{abef}$, namely the product ${}^*R\,R$ of the Riemann tensor with its dual, is the invariant characterizing the Thirring–Lense effect.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the help of the Riemann tensor by contraction, i.e., by setting

$$R_{bc} = R^{a}{}_{bac} \,. \tag{373}$$

Its components, like those of the Riemann tensor, are inverse square lengths. The values of the tensor R_{bc}, or those of R^{a}_{bcd}, are independent of the sign convention used in the Minkowski metric, in contrast to R_{abcd}.

Challenge 904 e

Challenge 905 ny

Can you confirm the relation $R_{abcd}R^{abcd} = 48m^2/r^6$ for the Schwarzschild solution?

Curiosities and fun challenges about general relativity

For a long time, people have speculated why the Pioneer 10 and 11 artificial satellites, which are now over 70 astronomical units away from the Sun, are subject to a constant deceleration of $8 \cdot 10^{-10}\ \mathrm{m/s^2}$ (towards the Sun) since they passed the orbit of Saturn. This effect is called the *Pioneer anomaly*. The origin is not clear and still a subject of research. But several investigations have shown that the reason is *not* a deviation from the inverse square dependence of gravitation, as is sometimes proposed. In other words, the effect must be electromagnetic.

Ref. 462

There are many hints that point to an asymmetry in heat radiation emission. Indeed, an front-to-back asymmetry of only 80 W is sufficient to explain the effect. (The on-board generators produce 2.5 kW.) But the source of the asymmetry has not been understood yet. Finding the asymmetry – or another explanation for the deceleration – is one of the challenges of modern space physics.

Ref. 463

Challenge 906 r

Test yourself: could the light mill effect, namely that impinging light pulls the object towards the source, be the reason for the effect?

Chapter 19

WHY CAN WE SEE THE STARS? – MOTION IN THE UNIVERSE

> Zwei Dinge erfüllen das Gemüt mit immer neuer und zunehmender Bewunderung und Ehrfurcht, je öfter und anhaltender sich das Nachdenken damit beschäftigt: der bestirnte Himmel über mir und das moralische Gesetz in mir.*
>
> Immanuel Kant (1724–1804)

On clear nights, between two and five thousand stars are visible with the naked eye. Several hundred of them have names. Indeed, in all parts of the world, the stars and the constellations they form are seen as memories of ancient events, and stories are told about them.** But the simple fact that we can *see* the stars is the basis for a story much more fantastic than all myths. It touches almost all aspects of modern physics.

Which stars do we see?

> Democritus says [about the Milky Way] that it is a region of light emanating from numerous stars small and near to each other, of which the grouping produces the brightness of the whole.
>
> Aetius, *Opinions*. Ref. 465

The stars we see on a clear night are mainly the brightest of our nearest neighbours in the surrounding region of the Milky Way. They lie at distances between four and a few thousand light years from us. Roughly speaking, in our environment there is a star about every 400 cubic light years.

Almost all visible stars are from our own galaxy. The only extragalactic object *constantly* visible to the naked eye in the northern hemisphere is the so-called Andromeda nebula, shown enlarged in Figure 292. It is a whole galaxy like our own, as Immanuel Kant had already conjectured in 1755. Several extragalactic objects are visible with the naked eye in the southern hemisphere: the Tarantula nebula, as well as the large and the small Magellanic clouds. The Magellanic clouds are neighbour galaxies to our own. Other, temporary exceptions are the rare *novae*, exploding stars which can be seen if they

* 'Two things fill the mind with ever new and increasing admiration and awe, the more often and persistently thought considers them: the starred sky above me and the moral law inside me.' Ref. 464

** About the myths around the stars and the constellations, see e.g. the text by G. Fasching, *Sternbilder und ihre Mythen*, Springer Verlag, 1993. On the internet there are also the beautiful www.astro.wisc.edu/~dolan/constellations/ and www.astro.uiuc.edu/~kaler/sow/sow.html websites.

FIGURE 292 The Andromeda nebula M31, our neighbour galaxy (and the 31st member of the Messier object listing) (NASA)

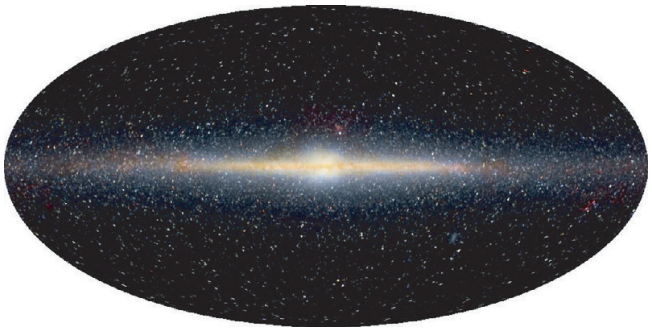

FIGURE 293 How our galaxy looks in the infrared (NASA)

appear in nearby galaxies, or the still rarer *supernovae*, which can often be seen even in faraway galaxies.

In fact, the visible stars are special in other respects also. For example, telescopes show that about half of them are in fact double: they consist of two stars circling around each other, as in the case of Sirius. Measuring the orbits they follow around each other allows one to determine their masses. Can you explain how?

Challenge 908 ny

Is the universe different from our Milky Way? Yes, it is. There are several arguments to demonstrate this. First of all, our galaxy – the word *galaxy* is just the original Greek term for 'Milky Way' – is *flattened*, because of its rotation. If the galaxy rotates, there must be other masses which determine the background with respect to which this rotation takes place. In fact, there is a huge number of other galaxies – about 10^{11} – in the universe, a discovery dating only from the twentieth century.

Why did our understanding of the place of our galaxy in the universe happen so late? Well, people had the same difficulty as they had when trying to determine the shape of the Earth. They had to understand that the galaxy is not only a milky strip seen on clear nights, but an actual physical system, made of about 10^{11} stars gravitating around each other.* Like the Earth, the galaxy was found to have a three-dimensional *shape*; it

* The Milky Way, or *galaxy* in Greek, was said to have originated when Zeus, the main Greek god, tried to let his son Heracles feed at Hera's breast in order to make him immortal; the young Heracles, in a sign

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 294 The elliptical galaxy NGC 205 (the 205th member of the New Galactic Catalogue) (NASA)

is shown in Figure 293. Our galaxy is a flat and circular structure, with a diameter of 100 000 light years; in the centre, it has a spherical bulge. It rotates about once every 200 to 250 million years. (Can you guess how this is measured?) The rotation is quite slow: since the Sun was formed, it has made only about 20 to 25 full turns around the centre.

Challenge 909 ny

It is even possible to measure the *mass* of our galaxy. The trick is to use a binary pulsar on its outskirts. If it is observed for many years, one can deduce its acceleration around the galactic centre, as the pulsar reacts with a frequency shift which can be measured on Earth. Many decades of observation are needed and many spurious effects have to be eliminated. Nevertheless, such measurements are ongoing. Present estimates put the mass of our galaxy at 10^{42} kg or $5 \cdot 10^{11}$ solar masses.

Ref. 468

What do we see at night?

Astrophysics leads to a strange conclusion about matter, quite different from how we are used to thinking in classical physics: *the matter observed in the sky is found in clouds*. *Clouds* are systems in which the matter density diminishes with the distance from the centre, with no definite border and with no definite size. Most astrophysical objects are best described as clouds.

The Earth is also a cloud, if we take its atmosphere, its magnetosphere and the dust ring around it as part of it. The Sun is a cloud. It is a gas ball to start with, but is even more a cloud if we take into consideration its protuberances, its heliosphere, the solar wind it generates and its magnetosphere. The solar system is a cloud if we consider its

showing his future strength, sucked so forcefully that the milk splashed all over the sky.

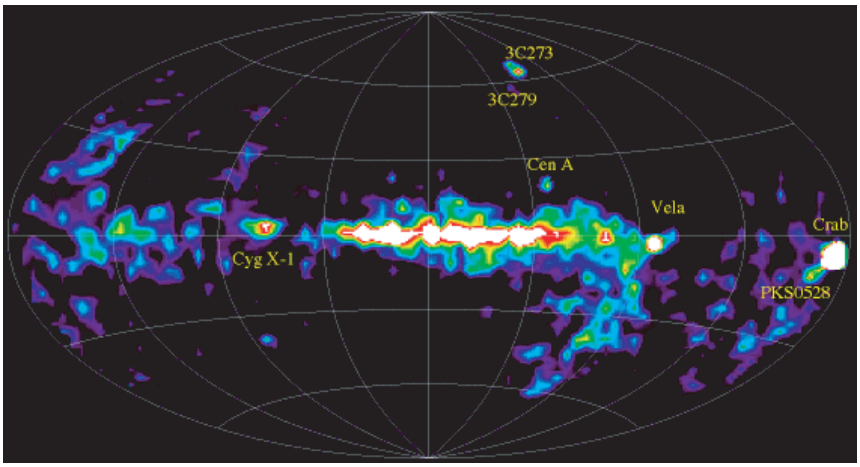

FIGURE 296 The X-rays in the night sky, between 1 and 30 MeV (NASA)

comet cloud, its asteroid belt and its local interstellar gas cloud. The galaxy is a cloud if we remember its matter distribution and the cloud of cosmic radiation it is surrounded by. In fact, even people can be seen as clouds, as every person is surrounded by gases, little dust particles from skin, vapour, etc.

Ref. 466 In the universe, almost all clouds are plasma clouds. A *plasma* is an ionized gas, such as fire, lightning, the inside of neon tubes, or the Sun. At least 99.9 % of all *matter in the universe is in the form of plasma clouds*. Only a very small percentage exists in solid or liquid form, such as toasters, subways or their users.

Clouds in the universe have certain common properties. First, clouds seen in the universe, when undisturbed by collisions or other interactions from neighbouring objects,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

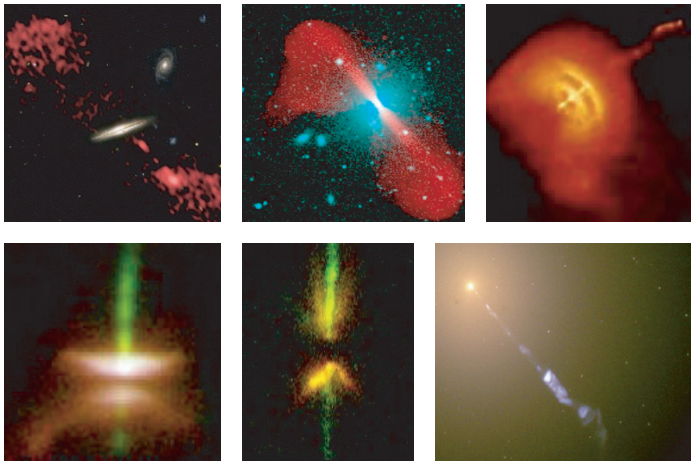

FIGURE 297 Rotating clouds emitting jets along their axis; top row: a composite image (visible and infrared) of the galaxy 0313-192, the galaxy 3C296, and the Vela pulsar; bottom row: the star in formation HH30, the star in formation DG Tauri B, and a black hole jet from the galaxy M87 (all NASA)

are *rotating*. Most clouds are therefore flattened and are in shape of discs. Secondly, in many rotating clouds, matter is falling towards the centre: most clouds are *accretion discs*. Finally, undisturbed accretion discs usually emit something along the rotation axis: they possess *jets*. This basic cloud structure has been observed for young stars, for pulsars, for galaxies, for quasars and for many other systems. Figure 297 gives some examples. (Does the Sun have a jet? Does the Milky Way have a jet? So far, none has been detected – there is still room for discovery.)

Challenge 910 r

In summary, at night we see mostly rotating, flattened plasma clouds emitting jets along their axes. A large part of astronomy and astrophysics collects information about them. An overview about the observations is given in Table 53.

Ref. 467

TABLE 53 Some observations about the universe

Aspect	Main properties	Value
Phenomena		
galaxy formation	observed by Hubble	several times
	trigger event	unknown
galactic collisions	momentum	10^{45} to 10^{47} kg m/s
star formation	cloud collapse	form stars between 0.04 and 200 solar masses
	frequency	between 0 and 1000 solar masses per year per galaxy; around 1 solar mass in the Milky Way
novae	new luminous stars,	$L < 10^{31}$ W
	ejecting bubble	$R \approx t \cdot c/100$
supernovae	new bright stars,	$L < 10^{36}$ W

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Aspect	Main properties	Value
	rate	1 to 5 per galaxy per 1000 a
hypernovae	optical bursts	$L > 10^{37}$ W
gamma-ray bursts	luminosity	L up to 10^{45} W, about one per cent of the whole visible universe's luminosity
	energy	*c.* 10^{46} J
	duration	*c.* 0.015 to 1000 s
	observed number	*c.* 2 per day
radio sources	radio emission	$10^{3}{}^{3}$ to 10^{38} W
X-ray sources	X-ray emission	$10^{2}{}^{3}$ to 10^{34} W
cosmic rays	energy	from 1 eV to 10^{22} eV
gravitational lensing	light bending	angles down to 10^{-4} ″
comets	recurrence, evaporation	typ. period 50 a, typ. visibility lifetime 2 ka, typ. lifetime 100 ka
meteorites	age	up to $4.57 \cdot 10^{9}$ a
Observed components		
intergalactic space	mass density	*c.* 10^{-26} kg/m^3
quasars	red-shift	up to $z = 6$
	luminosity	$L = 10^{40}$ W, about the same as one galaxy
galaxy superclusters	number of galaxies	*c.* 10^{8} inside our horizon
our own local supercluster	number of galaxies	about 4000
galaxy groups	size	100 Zm
	number of galaxies	between a dozen and 1000
our local group	number of galaxies	30
galaxies	size	0.5 to 2 Zm
	number	*c.* 10^{11} inside horizon
	containing	10 to 400 globular clusters
	containing	typically 10^{11} stars each
	containing	typically one supermassive and several intermediate-mass black holes
our galaxy	diameter	1.0(0.1) Zm
	mass	10^{42} kg or $5 \cdot 10^{11}$ solar masses Ref. 468
	speed	600 km/s towards Hydra-Centaurus
	containing	about 30 000 pulsars Ref. 469
	containing	100 globular clusters each with 1 million stars
globular clusters (e.g. M15)	containing	thousands of stars, one intermediate-mass black hole
	age	up to 12 Ga (oldest known objects)
nebulae, clouds	composition	dust, oxygen, hydrogen

Aspect	Main properties	Value
dimensions	number	3 for space, 1 for time, at low and moderate energies
matter	density	2 to 11 $\cdot 10^{-27}$ kg/m^3 or 1 to 6 hydrogen atoms per cubic metre
		$\Omega_M = 0.25$
baryons	density	$\Omega_b = 0.04$, one sixth of the previous (included in Ω_M)
dark matter	density	$\Omega_{DM} = 0.21$ (included in Ω_M), unknown
dark energy	density	$\Omega_{DM} = 0.75$, unknown
photons	number density	4 to 5 $\cdot 10^8$ /m^3 = 1.7 to 2.1 $\cdot 10^{-31}$ kg/m^3
	energy density	$\Omega_R = 4.6 \cdot 10^{-5}$
neutrinos	energy density	Ω_ν unknown
average temperature	photons	2.725(2) K
	neutrinos	not measured, predicted value is 2 K
perturbations	photon anisotropy	$\Delta T/T = 1 \cdot 10^{-5}$
	density amplitude	$A = 0.8(1)$
	spectral index	$n = 0.97(3)$
	tensor-to-scalar ratio	$r < 0.53$ with 95% confidence
ionization optical depth		$\tau = 0.15(7)$
decoupling		$z = 1100$

But while we are speaking of what we see in the sky, we need to clarify a general issue.

What is the universe?

> I'm astounded by people who want to 'know' the universe when it's hard enough to find your way around Chinatown.
>
> Woody Allen

The term universe implies turning. The universe is what turns around us at night. For a physicist, at least three definitions are possible for the term 'universe':

— The (*visible*) *universe* is the totality of all observable mass and energy. This includes everything inside the cosmological horizon. Since the horizon is moving away from us, the amount of observable mass and energy is constantly increasing. The content of the term 'visible universe' is thus not fixed in time. (What is the origin of this increase? We will come back to this issue later on.)

— The (*believed*) *universe* is the totality of all mass and energy, *including* any that is not visible. Numerous books on general relativity state that there definitely exists matter or energy beyond the observation boundaries. We will explain the origin of this belief below.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 298 The universe is full of galaxies – this photograph shows the Perseus cluster (NASA)

— The (*full*) *universe* is the sum of matter and energy *as well as* space-time itself.

These definitions are often mixed up in physical and philosophical discussions. There is *no* generally accepted consensus on the terms, so one has to be careful. In this text, when we use the term 'universe', we imply the *last* definition only. We will discover repeatedly that without clear distinction between the definitions the complete ascent of Motion Mountain becomes impossible. (For example: Is the amount of matter and energy in the full universe the same as in the visible universe?)

Challenge 911 ny

Note that the 'size' of the visible universe, or better, the distance to its horizon, is a quantity which *can* be imagined. The value of 10^{26} m is not beyond imagination. If one took all the iron from the Earth's core and made it into a wire reaching to the edge of the visible universe, how thick would it be? The answer might surprise you. Also, the content of the universe is clearly finite. There are about as many visible *galaxies* in the universe as there are grains in a cubic metre of sand. To expand on the comparison, can you deduce how much space you would need to contain all the flour you would get if every little speck represented one star?

Challenge 912 ny

Challenge 913 ny

The colour and the motion of the stars

> Ἦ τοι μὲν πρώτιστα Χάος γένετ' ... *
>
> Hesiod, *Theogony*.

* 'Verily, at first chaos came to be ...'. The Theogony, attributed to the probably mythical Hesiodos, was finalized around 700 BCE. It can be read in English and Greek on the www.perseus.tufts.edu website. The famous quotation here is from verse 117.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Obviously, the universe is full of motion. To get to know the universe a bit, it is useful to measure the speed and position of as many objects in it as possible. In the twentieth century, a large number of such observations were obtained from stars and galaxies.
Challenge 914 s (Can you imagine how distance and velocity are determined?) This wealth of data can be summed up in two points.

First of all, on large scales, i.e., averaged over about five hundred million light years, the matter density in the universe is *homogeneous* and *isotropic*. Obviously, at smaller scales inhomogeneities exist, such as galaxies or cheesecakes. Our galaxy for example is
Ref. 474 neither isotropic nor homogeneous. But at large scales the differences average out. This large-scale homogeneity of matter distribution is often called the *cosmological principle*.

The second point about the universe is even more important. In the 1920s, independ-
Ref. 475 ently, Carl Wirtz, Knut Lundmark and Gustaf Stromberg showed that on the whole, galaxies move away from the Earth, and the more so, the more they were distant. There are a few exceptions for nearby galaxies, such as the Andromeda nebula itself; but in general, the speed of flight v of an object increases with distance d. In 1929, the US-American astronomer Edwin Hubble* published the first measurement of the relation between speed and distance. Despite his use of incorrect length scales he found a relation

$$v = H\, d\ , \tag{374}$$

where the proportionality constant H is today called the *Hubble constant*. A graph of the relation is given in Figure 300. The Hubble constant is known today to have a value around $71\,\mathrm{km\,s^{-1}Mpc^{-1}}$. (Hubble's own value was so far from this value that it is not cited any more.) For example, a star at a distance of 2 Mpc** is moving away from Earth with a speed between of around 142 km/s, and proportionally more for stars further away.

In fact, the discovery by Wirtz, Lundmark and Stromberg implies that *every* galaxy
Challenge 915 ny moves away from *all* the others. (Why?) In other words, the matter in the universe is *expanding*. The scale of this expansion and the enormous dimensions involved are amazing. The motion of all the thousand million galaxy groups in the sky is described by the single equation (374)! Some deviations are observed for nearby galaxies, as mentioned above, and for faraway galaxies, as we will see.

The cosmological principle and the expansion taken together imply that the universe cannot have existed before time when it was of vanishing size; the universe thus has a *finite age*. Together with the evolution equations, as explained in more detail below, the Hubble constant points to an age value of around 13 700 million years. The expansion also means that the universe has a *horizon*, i.e., a finite maximum distance for sources whose signals can arrive on Earth. Signals from sources beyond the horizon cannot reach us.

Since the universe is expanding, in the past it has been much smaller and thus much denser than it is now. It turns out that it has also been hotter. George Gamow*** predicted

* Edwin Powell Hubble (1889–1953), important US-American astronomer. After being an athlete and taking a law degree, he returned to his childhood passion of the stars; he finally proved Immanuel Kant's 1755 conjecture that the Andromeda nebula was a galaxy like our own. He thus showed that the Milky Way is only a tiny part of the universe.

Page 923 ** A *megaparsec* or Mpc is a distance of 30.8 Zm.

*** George Gamow (b. 1904 Odessa, d. 1968 St. Boulder), Russian-American physicist; he explained alpha

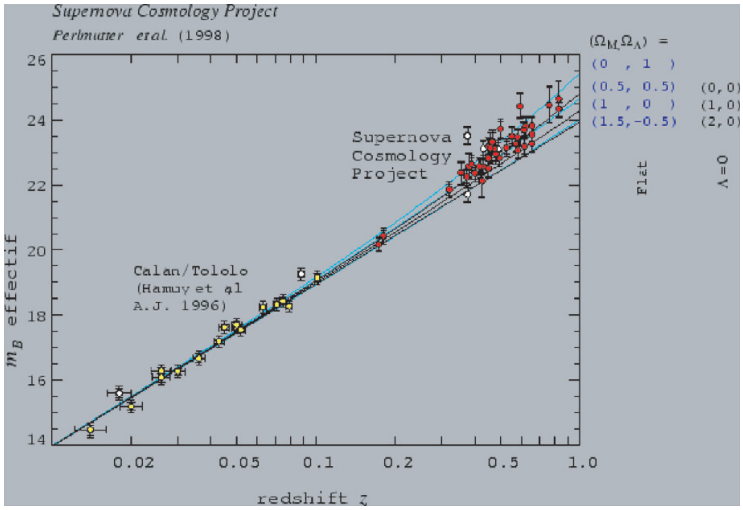

FIGURE 300 The relation between star distance and star velocity

Ref. 476 in 1948 that since hot objects radiate light, the sky cannot be completely black at night, but must be filled with black-body radiation emitted when it was 'in heat'. That radiation, called the *background radiation*, must have cooled down due to the expansion of the Challenge 916 ny universe. (Can you confirm this?) Despite various similar predictions by other authors, in one of the most famous cases of missed scientific communication, the radiation was found only much later, by two researchers completely unaware of all this work. A famous Ref. 477 paper in 1964 by Doroshkevich and Novikov had even stated that the antenna used by the (unaware) later discoverers was the best device to search for the radiation! In any case, only in 1965 did Arno Penzias and Robert Wilson discover the radiation. It was in one of the most beautiful discoveries of science, for which both later received the Nobel Ref. 478 Prize for physics. The radiation turns out to be described by the black-body radiation for a body with a temperature of 2.7 K; it follows the black-body dependence to a precision of about 1 part in 10^4.

But apart from expansion and cooling, the past fourteen thousand million years have also produced a few other memorable events.

Do stars shine every night?

> Don't the stars shine beautifully? I am the only person in the world who knows why they do.
> Friedrich (Fritz) Houtermans (1903–1966)

Stars seem to be there for ever. In fact, every now and then a new star appears in the sky: a *nova*. The name is Latin and means 'new'. Especially bright novae are called *supernovae*. Novae and similar phenomena remind us that stars usually live much longer than humans, but that like us, they are born, shine and die.

decay as a tunnelling effect and predicted the microwave background. He wrote the first successful popular science texts, such as *1, 2, 3, infinity* and the *Mr. Thompkins* series, which were later imitated by many others.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

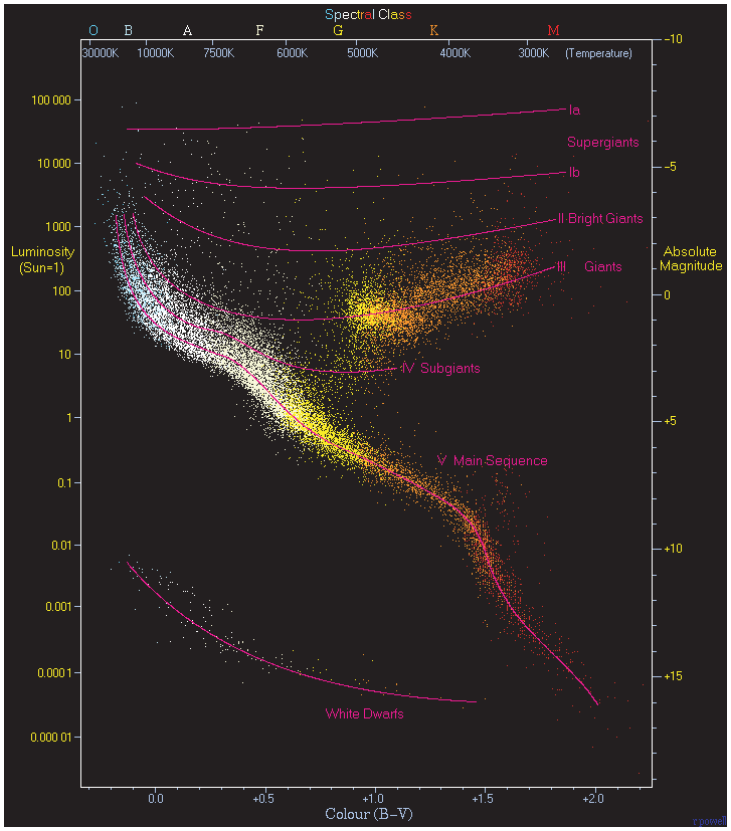

FIGURE 301 The Hertzsprung–Russell diagram (© Richard Powell)

It turns out that one can plot all stars on the so-called *Hertzsprung–Russell diagram*. This diagram, central to every book on astronomy, is shown in Figure 301. It is a beautiful example of a standard method used by astrophysicists: collecting statistics over many examples of a type of object, one can deduce the life cycle of the object, even though their lifetime is much longer than that of a human. For example, it is possible, by clever use of the diagram, to estimate the age of stellar clusters, and thus arrive at a minimum age of the universe. The result is around thirteen thousand million years.

The finite lifetime of stars leads to restrictions on their visibility, especially for high red-shifts. Indeed, modern telescope can look at places (and times) so far in the past that they contained no stars yet. At those distances one only observes *quasars*; these light sources are not stars, but much more massive and bright systems. Their precise structure is still being studied by astrophysicists.

Since the stars shine, they were also *formed* somehow. Over millions of years, vast dust clouds in space can contract, due to the influence of gravity, and form a dense, hot and rotating structure: a new star. The fascinating details of their birth from dust clouds are a central part of astrophysics, but we will not explore them here.

Yet we do not have the full answer to our question. Why do stars shine at all? Clearly, they shine because they are hot. They are hot because of nuclear reactions in their interior.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Page 1250 We will discuss these processes in more detail in the chapter on the nucleus.

A SHORT HISTORY OF THE UNIVERSE

> Anima scintilla stellaris essentiae.*
> Heraclitus of Ephesus (*c.* 540 to *c.* 480 BCE)

Ref. 479

Ref. 480 The adventures the universe has experienced, or better, the adventures the matter and radiation inside it have experienced, are summarized in Table 54. The steps not yet discussed will be studied in quantum theory. This history table has applications no theoretical physicist would have imagined. The sequence is so beautiful and impressive that nowadays it is used in certain psychotherapies to point out to people the story behind their existence and to remind them of their own worth. Enjoy.

TABLE 54 A short history of the universe

TIME FROM NOW[a]	TIME FROM BIG BANG[b]	EVENT	TEMPERATURE
$\approx 14 \cdot 10^9$ a	$\approx t_{\mathrm{Pl}}$ [b]	Time, space, matter and initial conditions indeterminate	10^{32} K $\approx T_{\mathrm{Pl}}$
$13 \cdot 10^9$ a	*c.* 800 t_{Pl} $\approx 10^{-42}$ s	Distinction of space-time from matter and radiation, initial conditions determinate	10^{30} K
	10^{-35} s to 10^{-32} s	**Inflation & GUT epoch** starts; strong and electroweak interactions diverge	$5 \cdot 10^{26}$ K
	10^{-12} s	Antiquarks annihilate; electromagnetic and weak interaction separate	10^{15} K
	$2 \cdot 10^{-6}$ s	Quarks get confined into hadrons; universe is a plasma	10^{13} K
		Positrons annihilate	
	0.3 s	Universe becomes transparent for neutrinos	10^{10} K
	a few seconds	**Nucleosynthesis**: D, ^{4}He, ^{3}He and ^{7}Li *nuclei* form; radiation still dominates	10^9 K
	2500 a	**Matter domination** starts; density perturbations magnify	75 000 K
$z = 1100$	380 000 a	**Recombination**: during these latter stages of the big bang, H, He and Li *atoms* form, and the universe becomes 'transparent' for light, as matter and radiation decouple, i.e., as they acquire different temperatures; the 'night' sky starts to get darker and darker	3000 K
		Sky is almost black except for black-body radiation	$T_\gamma = T_0(1+z)$
$z = 10$ to 30		**Galaxy formation**	
$z = 6$		Oldest object seen so far	

* 'The soul is a spark of the substance of the stars.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Time from now[a]	Time from big bang[b]	Event	Temperature
$z = 5$		Galaxy clusters form	
$z = 3$	10^6 a	First generation of stars (population II) is formed, starting hydrogen fusion; helium fusion produces carbon, silicon and oxygen	
	$2 \cdot 10^9$ a	First stars explode as supernovae[c]; iron is produced	
$z = 1$	$3 \cdot 10^9$ a	Second generation of stars (population I) appears, and subsequent supernova explosions of the ageing stars form the trace elements (Fe, Se, etc.) we are made of and blow them into the galaxy	
$4.7 \cdot 10^9$ a		Primitive cloud, made from such explosion remnants, collapses; Sun forms	
$4.6 \cdot 10^9$ a		**Earth** and other planet **formation**: Azoicum starts	
$4.3 \cdot 10^9$ a		Craters form on the planets	
$4.0 \cdot 10^9$ a		Moon forms from material ejected during the collision of a large asteroid with the still-liquid Earth	
$4.0 \cdot 10^9$ a		**Archean** eon (Archaeozoicum) starts: bombardment from space stops; Earth's crust solidifies; oldest minerals form; water condenses	
$3.5 \cdot 10^9$ a		Unicellular (microscopic) life appears; stromatolites form	
$2.5 \cdot 10^9$ a		**Proterozoic** eon ('age of first life') starts: atmosphere becomes rich in oxygen thanks to the activity of microorganisms Ref. 481	
$1 \cdot 10^9$ a		Macroscopic, multicellular life appears	
$800 \cdot 10^6$ a		Earth is completely covered with ice for the first time (reason still unknown) Ref. 482	
600 to $540 \cdot 10^6$ a		Earth is completely covered with ice for the last time	
$540(5) \cdot 10^6$ a		**Paleozoic** era (Palaeozoicum, 'age of old life') starts, after a gigantic ice age: animals appear, oldest fossils (with 540(5) start of Cambrian, 495(5) Ordovician, 440(5) Silurian, 417(5) Devonian, 354(5) Carboniferous and 292(5) Permian periods)	
$450 \cdot 10^6$ a		Land plants appear	
$370 \cdot 10^6$ a		Wooden trees appear	
$250(5) \cdot 10^6$ a		**Mesozoic** era (Mesozoicum, 'age of middle life', formerly called Secondary) starts: most insects and other life forms are exterminated; mammals appear (with 250(5) start of Triassic, 205(4) Jurassic and 142(3) Cretaceous periods)	
$150 \cdot 10^6$ a		Continent Pangaea splits into Laurasia and Gondwana	

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Time from now[a]	Time from big bang[b]	Event	Temperature
		The star cluster of the Pleiades forms	
$150 \cdot 10^6$ a		Birds appear	
$142(3) \cdot 10^6$ a		Golden time of dinosaurs (Cretaceous) starts	
$100 \cdot 10^6$ a		Start of formation of Alps, Andes and Rocky Mountains	
$65.5 \cdot 10^6$ a		**Cenozoic** era (Caenozoicum, 'age of new life') starts: dinosaurs become extinct after an asteroid hits the Earth in the Yucatan; primates appear (with 65.5 start of Tertiary, consisting of Paleogene period with Paleocene, 55.0 Eocene and 33.7 Oligocene epoch, and of Neogene period, with 23.8 Miocene and 5.32 Pliocene epoch; then 1.81 Quaternary period with Pleistocene (or Diluvium) and 0.01 Holocene (or Alluvium) epoch)	
$50 \cdot 10^6$ a		Large mammals appear	
$7(1) \cdot 10^6$ a		Hominids appears	
$3 \cdot 10^6$ a		Supernova explodes, with following consequences: more intense cosmic radiation, higher formation rate of clouds, Earth cools down drastically, high evolutionary pressure on the hominids and as a result, Homo appears Ref. 483	
500 000 a		Formation of youngest stars in galaxy	
500 000 a		Homo sapiens appears	
100 000 a		Beginning of last ice age	
90 000 a		Homo sapiens sapiens appears	
11 800 a		End of last ice age, start of Holocene	
6 000 a		First written texts	
2 500 a		Physics starts	
500 a		Use of coffee, pencil and modern physics starts	
200 a		Electricity use begins	
100 a		Einstein publishes	
10 to 120 a		You are a unicellular being	
present	*c.* $14 \cdot 10^9$ a	You are reading this	$T_\gamma = 2.73$ K, $T_\nu \approx 1.6$ K, $T_\mathrm{b} \approx 0$ K
future		You enjoy life; for details and reasons, see page 800	

a. The time coordinate used here is the one given by the coordinate system defined by the microwave background radiation, as explained on page 584. A year is abbreviated 'a' (Latin 'annus'). Errors in the last digits are given between parentheses.
b. This quantity is not exactly defined since the big bang is not a space-time event. More on this issue on page 1427.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

c. The history of the atoms on Earth shows that we are made from the leftovers of a supernova. We truly are made of *stardust*.

The geological time scale is the one of the International Commission on Stratigraphy; the times are measured through radioactive dating.

Despite its length and its interest, this table has its limitations. For example, what happened elsewhere in the last few thousand million years? There is still a story to be written of which next to nothing is known. For obvious reasons, investigations have been rather Earth-centred.

Research in astrophysics is directed at discovering and understanding all phenomena observed in the skies. Here we skip most of this fascinating topic, since as usual, we want to focus on motion. Interestingly, general relativity allows us to explain many of the general observations about motion in the universe.

The history of space-time

> A number of rabbits run away from a central point in various directions, all with the same speed. While running, one rabbit turns its head, and makes a startling observation. What does it see?

Challenge 917 s

The data showing that the universe is sprinkled with stars all over lead to a simple conclusion: the universe cannot be static. Gravity always changes the distances between bodies; the only exceptions are circular orbits. Gravity also changes the *average* distances between bodies: gravity always tries to collapse clouds. The biggest cloud of all, the one formed by all the matter in the universe, must therefore either be collapsing, or still be in expansion.

Ref. 484 The first to dare to draw this conclusion was Aleksander Friedmann.* In 1922 he deduced the detailed evolution of the universe in the case of homogeneous, isotropic mass distribution. His calculation is a classic example of simple but powerful reasoning. For a universe which is homogeneous and isotropic for every point, the line element is given by

Challenge 918 ny

$$ds^2 = c^2 dt^2 - a^2(t)(dx^2 + dy^2 + dz^2) \tag{375}$$

and matter is described by a density ρ_M and a pressure p_M. Inserting all this into the field

* Aleksander Aleksandrowitsch Friedmann (1888–1925), Russian physicist who predicted the expansion of the universe. Following his early death from typhus, his work remained almost unknown until Georges A. Lemaître (b. 1894 Charleroi, d. 1966 Leuven), Belgian priest and cosmologist, took it up and expanded it in 1927, focusing, as his job required, on solutions with an initial singularity. Lemaître was one of the propagators of the (erroneous!) idea that the big bang was an 'event' of 'creation' and convinced his whole organization of it. The Friedmann–Lemaître solutions are often erroneously called after two other physicists, who studied them again much later, in 1935 and 1936, namely H.P. Robertson and A.G. Walker.

Page 590, page 591

equations, we get two equations

$$\left(\frac{\dot{a}}{a}\right)^2 + \frac{k}{a^2} = \frac{8\pi G}{3}\rho_{\mathrm{M}} + \frac{\Lambda}{3} \quad \text{and} \tag{376}$$

$$\ddot{a} = -\frac{4\pi G}{3}(\rho_{\mathrm{M}} + 3p_{\mathrm{M}})\, a + \frac{\Lambda}{3}\, a \tag{377}$$

which imply

$$\dot{\rho}_{\mathrm{M}} = -3\frac{\dot{a}}{a}(\rho_{\mathrm{M}} + p_{\mathrm{M}}) \,. \tag{378}$$

At the present time t_0, the pressure of matter is negligible. (In the following, the index 0 refers to the present time.) In this case, the expression $\rho_{\mathrm{M}} a^3$ is constant in time.

Equations (376) and (377) depend on only two constants of nature: the gravitational constant G, related to the maximum force or power in nature, and the cosmological constant Λ, describing the energy density of the vacuum, or, if one prefers, the smallest force in nature.

Challenge 919 ny

Before we discuss the equations, first a few points of vocabulary. It is customary to relate all mass densities to the so-called *critical mass density* ρ_{c} given by

$$\rho_{\mathrm{c}} = \frac{3H_0^2}{8\pi G} \approx (8 \pm 2) \cdot 10^{-27}\,\mathrm{kg/m^3} \tag{379}$$

corresponding to about 8, give or take 2, hydrogen atoms per cubic metre. On Earth, one would call this value an extremely good *vacuum*. Such are the differences between everyday life and the universe as a whole. In any case, the critical density characterizes a matter distribution leading to an evolution of the universe just between never-ending expansion and collapse. In fact, this density is the critical one, leading to a so-called *marginal* evolution, only in the case of *vanishing* cosmological constant. Despite this restriction, the term is now used for this expression in all other cases as well. One thus speaks of dimensionless mass densities Ω_{M} defined as

$$\Omega_{\mathrm{M}} = \rho_0/\rho_{\mathrm{c}} \,. \tag{380}$$

The cosmological constant can also be related to this critical density by setting

$$\Omega_\Lambda = \frac{\rho_\Lambda}{\rho_{\mathrm{c}}} = \frac{\Lambda c^2}{8\pi G \rho_{\mathrm{c}}} = \frac{\Lambda c^2}{3H_0^2} \,. \tag{381}$$

A third dimensionless parameter Ω_{K} describes the curvature of space. It is defined in terms of the present-day radius of the universe R_0 and the curvature constant $k = \{1, -1, 0\}$ as

$$\Omega_{\mathrm{K}} = \frac{-k}{R_0^2\, H_0^2} \tag{382}$$

and its sign is opposite to the one of the curvature k; Ω_{K} vanishes for vanishing curvature.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

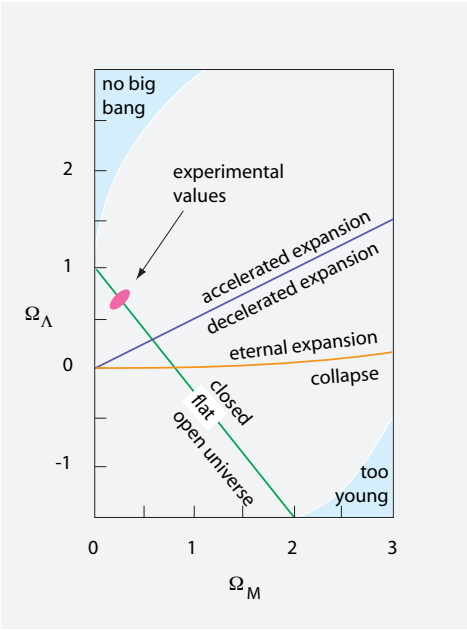

FIGURE 302 The ranges for the Ω parameters and their consequences

Note that a positively curved universe, when homogeneous and isotropic, is necessarily closed and of finite volume. A flat or negatively curved universe with the same matter distribution can be open, i.e., of infinite volume, but does not need to be so. It could be simply or multiply connected. In these cases the topology is not completely fixed by the curvature.

The present-time Hubble parameter is defined by $H_0 = \dot{a}_0/a_0$. From equation (376) we then get the central relation

Challenge 920 ny

$$\Omega_M + \Omega_\Lambda + \Omega_K = 1 \,. \tag{383}$$

In the past, when data were lacking, physicists were divided into two camps: the *claustrophobics* believing that $\Omega_K > 0$ and the *agoraphobics* believing that $\Omega_K < 0$. More details about the measured values of these parameters will be given shortly. The diagram of Figure 302 shows the most interesting ranges of parameters together with the corresponding behaviours of the universe.

For the Hubble parameter, the most modern measurements give a value of

$$H_0 = 71 \pm 4\,\mathrm{km/sMpc} = 2.3 \pm 2 \cdot 10^{-18}\,/\mathrm{s} \tag{384}$$

which corresponds to an age of the universe of 13.7 ± 2 thousand million years. In other words, the age deduced from the history of space-time agrees with the age, given above, deduced from the history of stars.

To get a feeling of how the universe evolves, it is customary to use the so-called *decel-*

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

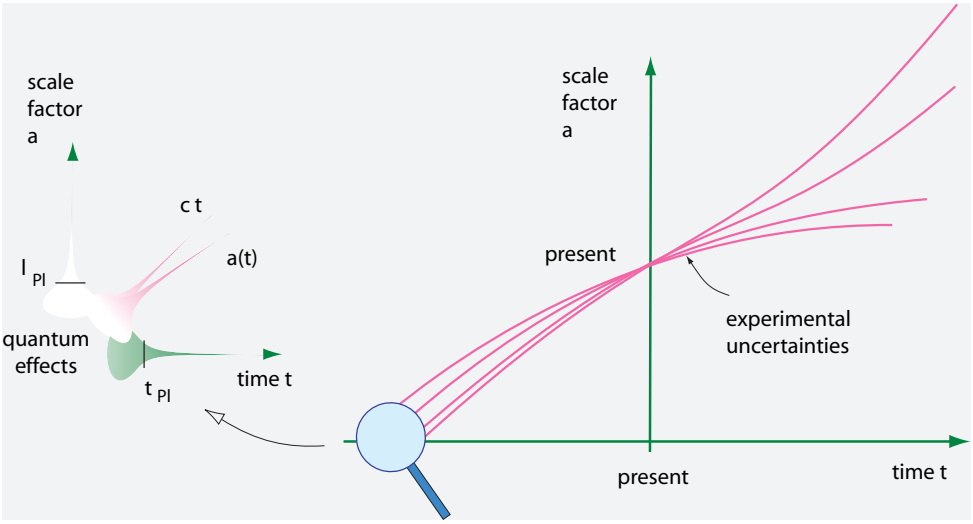

FIGURE 303 The evolution of the universe's scale a for different values of its mass density

eration parameter q_0. It is defined as

$$q_0 = -\frac{\ddot{a}_0}{a_0 H_0^2} = \frac{1}{2}\Omega_M - \Omega_\Lambda \,. \tag{385}$$

The parameter q_0 is positive if the expansion is slowing down, and negative if the expansion is accelerating. These possibilities are also shown in the diagram.

An even clearer way to picture the expansion of the universe for vanishing pressure is to rewrite equation (376) using $\tau = t\,H_0$ and $x(\tau) = a(t)/a(t_0)$, yielding

$$\begin{aligned} (\frac{\mathrm{d}x}{\mathrm{d}\tau})^2 + U(x) &= \Omega_K \\ \text{with } U(x) &= -\Omega_\Lambda x - \Omega_\Lambda x^2 \end{aligned} \tag{386}$$

This looks like the evolution equation for the motion of a particle with mass 1, with total energy Ω_K in a potential $U(x)$. The resulting evolutions are easily deduced.

For vanishing Ω_Λ, the universe either expands for ever, or recollapses, depending on the value of the mass–energy density.

For non-vanishing (positive) Ω_Λ, the potential has exactly one maximum; if the particle has enough energy to get over the maximum, it will accelerate continuously. That is the situation the universe seems to be in today.

For a certain time range, the result is shown in Figure 303. There are two points to be noted: first the set of possible curves is described by *two* parameters, not one. In addition, lines cannot be drawn down to zero size. There are two main reasons: we do not yet understand the behaviour of matter at very high energy, and we do not understand the behaviour of space-time at very high energy. We return to this important issue later on.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

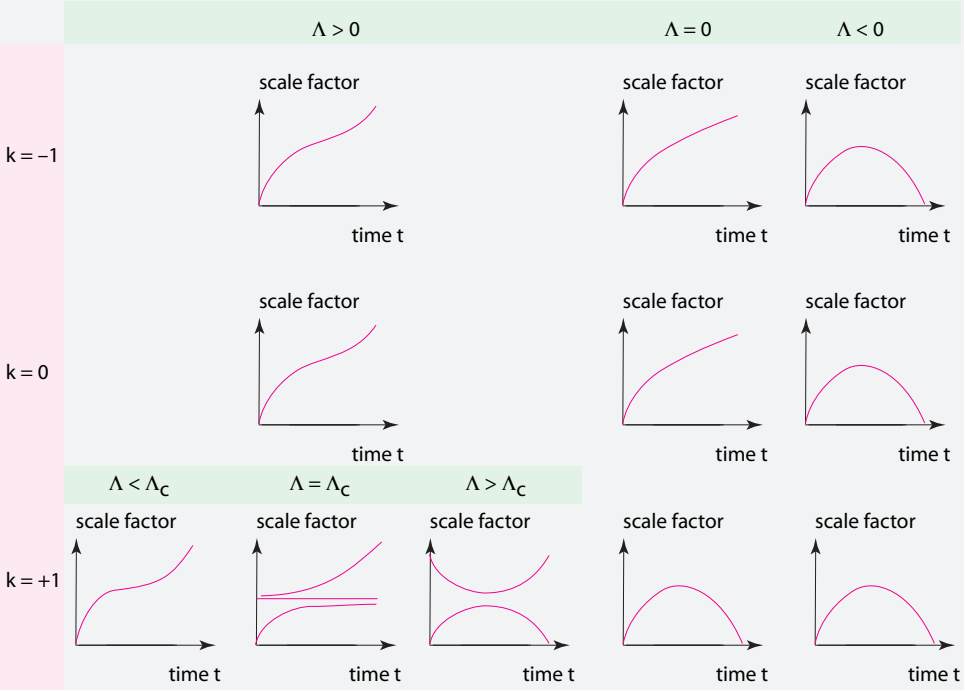

FIGURE 304 The long-term evolution of the universe's scale factor a for various parameters

The main conclusion to be drawn from Friedmann's work is that a homogeneous and isotropic universe is *not static*: it either expands or contracts. In either case, it has a *finite age*. This profound idea took many years to spread around the cosmology community; even Einstein took a long time to get accustomed to it.

Note that due to its isotropic expansion, the universe has a preferred reference frame: the frame defined by average matter. The time measured in that frame is the time listed in Table 54 and is the one we assume when we talk about the *age* of the universe.

An overview of the possibilities for the long time evolution is given in Figure 304. The evolution can have various outcomes. In the early twentieth century, people decided among them by personal preference. Albert Einstein first preferred the solution $k = 1$ and $\Lambda = a^{-2} = 4\pi G\rho_M$. It is the unstable solution found when $x(\tau)$ remains at the top of the potential $U(x)$.

In 1917, the Dutch physicist Willem de Sitter had found, much to Einstein's personal dismay, that an empty universe with $\rho_M = p_M = 0$ and $k = 1$ is also possible. This type of universe expands for large times. The de Sitter universe shows that in special cases, matter is not needed for space-time to exist.

Challenge 921 ny

Lemaître had found expanding universes for positive mass, and his results were also contested by Einstein at first. When later the first measurements confirmed the calculations, the idea of a massive and expanding universe became popular. It became the standard model in textbooks. However, in a sort of collective blindness that lasted from

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

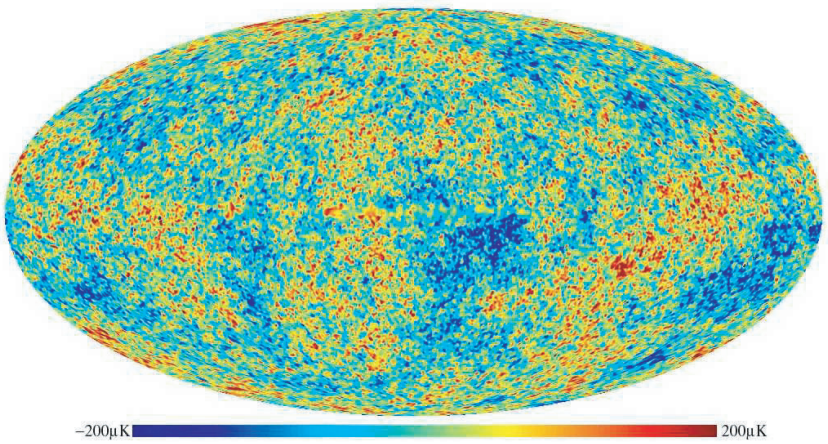

FIGURE 305 The fluctuations of the cosmic background radiation (WMAP/NASA)

around 1950 to 1990, almost everybody believed that $\Lambda = 0$.* Only towards the end of the twentieth century did experimental progress allow one to make statements based on evidence rather than beliefs or personal preferences, as we will find out shortly. But first of all we will settle an old issue.

Why is the sky dark at night?

> In der Nacht hat ein Mensch nur ein Nachthemd an, und darunter kommt gleich der Charakter.**
>
> Rober Musil

First of all, the sky is not black at night. It has the same intrinsic colour as during the day, as any long-exposure photograph shows. (See, for example, Figure 98.) But that colour, like the colour of the sky during the day, is not due to the temperature of the sky, but to scattered light from the stars. If we look for the real colour of the sky, we need to look for its thermal radiation. Indeed, measurements show that even the empty sky is not completely cold or black at night. It is filled with radiation of around 200 GHz; more precise measurements show that the radiation corresponds to the thermal emission of a body at 2.73 K. This *background radiation* is the thermal radiation left over from the big bang.

Ref. 485 The universe is indeed colder than the stars. But why is this so? If the universe were homogeneous on large scales and infinitely large, it would have an infinite number of stars. Looking in any direction, we would see the surface of a star. The night sky would Challenge 923 s be as bright as the surface of the Sun! Can you convince your grandmother about this?

In a deep forest, one sees a tree in every direction. Similarly, in a 'deep' universe, we

Challenge 922 ny * In this case, for $\Omega_M \geqslant 1$, the age of the universe follows $t_0 \leqslant 2/(3H_0)$, where the limits correspond. For vanishing mass density one has $t_0 = 1/H_0$.

** 'At night, a person is dressed only with a nightgown, and directly under it there is the character.' Robert Musil (b. 1880 Klagenfurt, d. 1942 Geneva), German writer.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

would see a star in every direction. Now, the average star has a surface temperature of about 6000 K. If we lived in a deep and old universe, we would effectively live inside an oven with a temperature of around 6000 K, making it impossible to enjoy ice cream.

This paradox was most clearly formulated in 1823 by the astronomer Wilhelm Olbers.* As he extensively discussed the question, it is also called *Olbers' paradox*. Today we know that even if all matter in the universe were converted into radiation, the universe would still not be as bright as just calculated. In other words, the power and lifetime of stars are much too low to produce the oven brightness just mentioned. So something is wrong.

Ref. 486

In fact, two main effects can be invoked to avoid the contradiction. First, since the universe is finite in age, distant stars are shining for less time. We see them in a younger stage or even during their formation, when they were darker. As a result, the share of brightness of distant stars is smaller than that of nearby stars, so that the average temperature of the sky is reduced.** Secondly, we could imagine that the radiation of distant stars is red-shifted and that the volume the radiation must fill is increasing continuously, so that the average temperature of the sky is also reduced.

Calculations are necessary to decide which effect is the greater one. This issue has been studied in great detail by Paul Wesson; he explains that the first effect is larger than the second by a factor of about three. We may thus state correctly that the sky is dark at night *mostly* because the universe has a finite age. We can add that the sky would be somewhat brighter if the universe were not expanding.

Ref. 487

Ref. 485

In addition, the darkness of the sky is possible only because the speed of light is finite. Can you confirm this?

Challenge 925 ny

Finally, the darkness of the sky also tells us that the universe has a *large* (but finite) age. Indeed, the 2.7 K background radiation is that cold, despite having been emitted at 3000 K, because it is red-shifted, thanks to the Doppler effect. Under reasonable assumptions, the temperature T of this radiation changes with the scale factor $R(t)$ of the universe as

Ref. 488

$$T \sim \frac{1}{R(t)} \,. \tag{387}$$

In a young universe, we would thus not be able to see the stars, even if they existed.

From the brightness of the sky at night, measured to be about $3 \cdot 10^{-13}$ times that of an average star like the Sun, we can deduce something interesting: the density of stars in the universe must be much smaller than in our galaxy. The density of stars in the galaxy can be deduced by counting the stars we see at night. But the average star density in the galaxy would lead to much higher values for the night brightness if it were constant throughout the universe. We can thus deduce that the galaxy is much *smaller* than the

Ref. 486

* Heinrich Wilhelm Matthäus Olbers (b. 1758 Arbergen, d. 1840 Bremen), astronomer. He discovered two planetoids, Pallas and Vesta, and five comets; he developed the method of calculating parabolic orbits for comets which is still in use today. Olbers also actively supported the mathematician and astronomer Friedrich Wilhelm Bessel in his career choice. The paradox is named after Olbers, though others had made similar points before, such as the Swiss astronomer Jean Philippe Loÿs de Cheseaux in 1744 and Johannes Kepler in 1610.

Page 126

** Can you explain that the sky is not black just because it is painted black or made of black chocolate? Or more generally, that the sky is not made of and does not contain any dark and cold substance, as Olbers himself suggested, and as John Herschel refuted in 1848?

Challenge 924 ny

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

universe simply by measuring the brightness of the night sky and by counting the stars in the sky! Can you make the explicit calculation? Challenge 926 ny

In summary, the sky is black at night because space-time and matter are of finite, but old age. As a side issue, here is a quiz: is there an Olbers' paradox also for gravitation? Challenge 927 ny

Is the universe open, closed or marginal?

> - Doesn't the vastness of the universe make you feel small?
> - I can feel small without any help from the universe.
>
> Anonymous

Sometimes the history of the universe is summed up in two words: *bang!...crunch*. But will the universe indeed recollapse, or will it expand for ever? Or is it in an intermediate, marginal situation? The parameters deciding its fate are the mass density and cosmological constant.

The main news of the last decade of twentieth-century astrophysics are the experimental results allowing one to determine all these parameters. Several methods are being used. The first method is obvious: determine the speed and distance of distant stars. For large distances, this is difficult, since the stars are so faint. But it has now become possible to search the sky for supernovae, the bright exploding stars, and to determine their distance from their brightness. This is presently being done with the help of computerized searches of the sky, using the largest available telescopes. Ref. 489

A second method is the measurement of the anisotropy of the cosmic microwave background. From the observed power spectrum as a function of the angle, the curvature of space-time can be deduced.

A third method is the determination of the mass density using the gravitational lensing effect for the light of distant quasars bent around galaxies or galaxy clusters. Page 595

A fourth method is the determination of the mass density using galaxy clusters. All these measurements are expected to improve greatly in the years to come.

At present, these four completely independent sets of measurements provide the values Ref. 490

$$(\Omega_M, \Omega_\Lambda, \Omega_K) \approx (0.3, 0.7, 0.0) \tag{388}$$

where the errors are of the order of 0.1 or less. The values imply that *the universe is spatially flat, its expansion is accelerating and there will be no big crunch*. However, no definite statement on the topology is possible. We will return to this last issue shortly. Page 596

In particular, the data show that the density of matter, including all dark matter, is only about one third of the critical value.* Two thirds are given by the cosmological term. For

* The difference between the total matter density and the separately measurable baryonic matter density, only about one sixth of the former value, is also not explained yet. It might even be that the universe contains matter of a type unknown so far. This issue is called the *dark matter problem*; it is one of the important unsolved questions of cosmology.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

the cosmological constant Λ one gets the value

$$\Lambda = \Omega_\Lambda \frac{3H_0^2}{c^2} \approx 10^{-52}/\mathrm{m}^2 \,. \tag{389}$$

This value has important implications for quantum theory, since it corresponds to a vacuum energy density

$$\rho_\Lambda c^2 = \frac{\Lambda c^4}{8\pi G} \approx 0.5\,\mathrm{nJ/m^3} \approx \frac{10^{-46}\,(\mathrm{GeV})^4}{(\hbar c)^3} \,. \tag{390}$$

But the cosmological term also implies a negative vacuum pressure $p_\Lambda = -\rho_\Lambda c^2$. Inserting this result into the relation for the potential of universal gravity deduced from relativity

Page 553

$$\Delta\varphi = 4\pi G(\rho + 3p/c^2) \tag{391}$$

Ref. 491 we get

$$\Delta\varphi = 4\pi G(\rho_\mathrm{M} - 2\rho_\Lambda) \,. \tag{392}$$

Challenge 928 ny Thus the gravitational acceleration is

$$a = \frac{GM}{r^2} - \frac{\Lambda}{3}c^2 r = \frac{GM}{r^2} - \Omega_\Lambda H_0^2\, r \,, \tag{393}$$

which shows that a *positive* vacuum energy indeed leads to a *repulsive* gravitational effect. Inserting the mentioned value (389) for the cosmological constant Λ we find that the repulsive effect is small even for the distance between the Earth and the Sun. In fact, the order of magnitude of the repulsive effect is so much smaller than that of attraction that one cannot hope for a direct experimental confirmation of this deviation from universal gravity at all. Challenge 929 ny Probably astrophysical determinations will remain the only possible ones. A positive gravitational constant manifests itself through a positive component in the expansion rate, as we will see shortly.

But the situation is puzzling. The origin of this cosmological constant is *not* explained by general relativity. This mystery will be solved only with the help of quantum theory. In any case, the cosmological constant is the first local and quantum aspect of nature detected by astrophysical means.

Why is the universe transparent?

Could the universe be filled with water, which is transparent, as maintained by some popular books in order to explain rain? Ref. 492 No. Even if it were filled with air, the total mass would never have allowed the universe to reach the present size; it would have recollapsed much earlier and we would not exist. Challenge 930 ny

The universe is thus transparent because it is mostly empty. But *why* is it so empty? First of all, in the times when the size of the universe was small, all antimatter annihilated with the corresponding amount of matter. Only a tiny fraction of matter, which originally

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

was slightly more abundant than antimatter, was left over. This 10^{-9} fraction is the matter
Page 1288 we see now. As a consequence, there are 10^9 as many photons in the universe as electrons or quarks.

In addition, 380 000 years after antimatter annihilation, all available nuclei and electrons recombined, forming atoms, and their aggregates, like stars and people. No free charges interacting with photons were lurking around any more, so that from that period onwards light could travel through space as it does today, being affected only when it hits a star or dust particle.

If we remember that the average density of the universe is $10^{-26}\,\mathrm{kg/m^3}$ and that most of the matter is lumped by gravity in galaxies, we can imagine what an excellent vacuum lies in between. As a result, light can travel along large distances without noticeable hindrance.

But why is the vacuum transparent? That is a deeper question. Vacuum is transparent because it contains no electric charges and no horizons: charges or horizons are indispensable in order to absorb light. In fact, quantum theory shows that vacuum does
Page 1189 contain so-called *virtual* charges. However, virtual charges have no effects on the transmission of light.

The big bang and its consequences

> Μελέτη θανάτου. Learn to die.
> Plato, *Phaedo*, 81a.

Above all, the big bang model, which is deduced from the colour of the stars and galaxies, states that about fourteen thousand million years ago the whole universe was extremely
Page 868 small. This fact gave the big bang its name. The term was created (with a sarcastic un-
Ref. 493 dertone) in 1950 by Fred Hoyle, who by the way never believed that it applies to nature. Nevertheless, the term caught on. Since the past smallness of the universe be checked directly, we need to look for other, verifiable consequences. The central ones are the following:

— all matter moves away from all other matter;
— the mass of the universe is made up of about 75% hydrogen and 23% helium;
— there is thermal background radiation of about 2.7 K;
— the maximal age for any system in the universe is around fourteen thousand million years;
— there are background neutrinos with a temperature of about 2 K;*
— for non-vanishing cosmological constant, Newtonian gravity is slightly reduced.

All predictions except the last two have been confirmed by observations. Technology will probably not allow us to check the last two in the foreseeable future; however, there is no evidence against them.

Competing descriptions of the universe have not been so successful in matching
Ref. 493 observations. In addition, theoretical arguments state that with matter distributions such as the observed one, and some rather weak general assumptions, there is no way to avoid
Ref. 494 a period in the *finite* past in which the universe was extremely small. Therefore it is worth

* The theory states that $T_\nu/T_\gamma \approx (4/11)^{1/3}$. These neutrinos appeared about 0.3 s after the big bang.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

having a close look at the situation.

Was the big bang a big bang?

Was it a kind of explosion? This description implies that some material transforms internal energy into motion of its parts. There was no such process in the early history of the universe. In fact, a better description is that space-time is expanding, rather than matter moving. The mechanism and the origin of the expansion is *unknown* at this point of our mountain ascent. Because of the importance of spatial expansion, the whole phenomenon cannot be called an explosion at all. And obviously there neither was nor is any sound carrying medium in interstellar space, so that one cannot speak of a 'bang' in any sense of the term.

Was it big? The visible universe was rather small about fourteen thousand million years ago, much smaller than an atom. In summary, the big bang was neither big nor a bang; but the rest is correct.

Was the big bang an event?

The big bang theory is a description of what happened in the *whole* of space-time. Despite what is often written in careless newspaper articles, at every moment of the expansion space has been of non-vanishing size: space was *never* a single point. People who pretend it was are making ostensibly plausible, but false statements. The big bang theory is a description of the *expansion* of space-time, not of its beginning. Following the motion of matter back in time, general relativity cannot deduce the existence of an initial singularity. The issue of measurement errors is probably not a hindrance; however, the effect of the nonlinearities in general relativity at situations of high energy densities is not clear.

Most importantly, quantum theory shows that the big bang was *not* a true singularity, as no physical observable, neither density nor temperature, ever reaches an infinitely large (or infinitely small) value. Such values cannot exist in nature.* In any case, there is a general agreement that arguments based on *pure* general relativity alone cannot make correct statements about the big bang. Nevertheless, most statements in newspaper articles are of this sort.

Page 1436

Was the big bang a beginning?

Asking what was before the big bang is like asking what is north of the North Pole. Just as nothing is north of the North Pole, so nothing 'was' before the big bang. This analogy could be misinterpreted to imply that the big bang took its start at a single point in time, which of course is incorrect, as just explained. But the analogy is better than it looks: in fact, there is *no* precise North Pole, since quantum theory shows that there is a fundamental indeterminacy as to its position. There is also a corresponding indeterminacy for the big bang.

In fact, it does not take more than three lines to show with quantum theory that time and space are *not* defined either at or near the big bang. We will give this simple argument in the first chapter of the final part of our mountain ascent. The big bang therefore cannot

Page 1401

* Many physicists are still wary of making such strong statements on this point. The first sections of the final part of our mountain ascent give the precise arguments leading to them.

Page 1396

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

be called a 'beginning' of the universe. There never was a time when the scale factor $a(t)$ of the universe was zero.

This conceptual mistake is frequently encountered. In fact, quantum theory shows that near the big bang, events can *neither* be ordered *nor* even be defined. More bluntly, there is *no* beginning; there has never been an initial event or singularity.

Obviously the concept of time is not defined 'outside' or 'before' the existence of the universe; this fact was already clear to thinkers over a thousand years ago. It is then tempting to conclude that time must have *started*. But as we saw, that is a logical mistake as well: first of all, there is no starting event, and secondly, time does not flow, as clarified already in the beginning of our walk.

Ref. 495 Page 51

A similar mistake lies behind the idea that the universe had certain 'initial conditions.' Initial conditions *by definition* make sense only for objects or fields, i.e., for entities which can be observed from the outside, i.e., for entities which have an environment. The universe does not comply with this requirement; it thus cannot have initial conditions. Nevertheless, many people still insist on thinking about this issue; interestingly, Stephen Hawking sold millions of copies of a book explaining that a description without initial conditions is the most appealing, overlooking the fact that there is no other possibility anyway.*

Page 185 Ref. 496

In summary, the big bang is not a beginning, nor does it imply one. We will uncover the correct way to think about it in the final part of our mountain ascent.

Does the big bang imply creation?

> "[The general theory of relativity produces] universal doubt about god and his creation."
>
> A witch hunter

Creation, i.e., the appearance of something out of nothing, needs an existing concept of space and time to make sense. The concept of 'appearance' makes no sense otherwise. But whatever the description of the big bang, be it classical, as in this chapter, or quantum mechanical, as in later ones, this condition is never fulfilled. Even in the present, classical description of the big bang, which gave rise to its name, there is *no* appearance of matter, nor of energy, nor of anything else. And this situation does not change in any later, improved description, as time or space are never defined *before* the appearance of matter.

Page 862

In fact, all properties of a creation are missing: there is no 'moment' of creation, no appearance from nothing, no possible choice of any 'initial' conditions out of some set of possibilities, and as we will see in more detail later on, not even any choice of particular physical 'laws' from any set of possibilities.

In summary, the big bang does not imply nor harbour a creation process. The big bang was not an event, not a beginning and *not* a case of creation. It is impossible to continue the ascent of Motion Mountain if one cannot accept each of these three conclusions. To deny them is to continue in the domain of beliefs and prejudices, thus effectively giving up on the mountain ascent.

Challenge 931 ny

* This statement will still provoke strong reactions among physicists; it will be discussed in more detail in the section on quantum theory.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

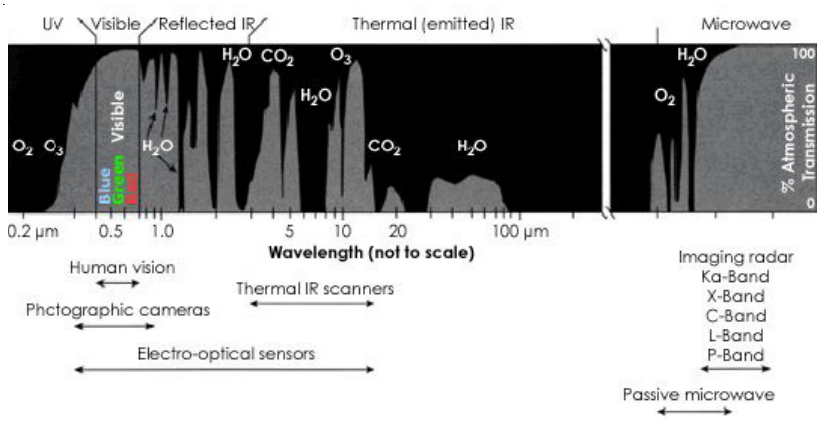

FIGURE 306 The transmittance of the atmosphere (NASA)

Note that this requirement is not new. In fact, it was already contained in equation (1) at the start of our walk, as well as in all the following ones. It appears even more clearly at this point. But what then *is* the big bang? We'll find out in the last part of our ascent. We now return to the discussion of what the stars can tell us about nature.

Page 54

Why can we see the Sun?

First of all, the Sun is visible because air is transparent. It is not self-evident that air is transparent; in fact it is transparent only to *visible* light and to a few selected other frequencies. Infrared and ultraviolet radiation are mostly absorbed. The reasons lie in the behaviour of the molecules the air consists of, namely mainly nitrogen, oxygen and a few other transparent gases. Several moons and planets in the solar system have opaque atmospheres: we are indeed lucky to be able to see the stars at all.

In fact, even air is not completely transparent; air molecules *scatter* light a little bit. That is why the sky and distant mountains appear blue and sunsets red,* and stars are invisible during daylight. At many wavelengths far from the visible spectrum the atmosphere is even opaque, as Figure 306 shows. (It is also opaque for all wavelengths shorter than 200 nm, up to gamma rays. On the long wavelength range, it remains transparent up to wavelength of around 10 to 20 m, depending on solar activity, when the extinction by the ionosphere sets in.)

Secondly, we can see the Sun because the Sun, like all hot bodies, *emits* light. We describe the details of *incandescence*, as this effect is called, below.

Page 793

Thirdly, we can see the Sun because we and our environment and the Sun's environment are *colder* than the Sun. In fact, incandescent bodies can be distinguished from their background only if the background is colder. This is a consequence of the properties of incandescent light emission, usually called *black-body radiation*. The radiation is

* Air scattering makes the sky blue also at night, as can be proven by long-exposure photographs. (See, for example, Figure 98.) However, our eyes are not able to perceive this, and the low levels of light make it appear black to us.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

material-independent, so that for an environment with the same temperature as the body, nothing can be seen at all. Just have a look at the photograph on page 770 as a proof.

Finally, we can see the Sun because it is not a black hole. If it were, it would emit (almost) no light.

Obviously, each of these conditions applies to stars as well. For example, we can only see them because the night sky is black. But then, how to explain the multicoloured sky?

Why are the colours of the stars different?

Stars are visible because they emit visible light. We have encountered several important effects which determine colours: the diverse temperatures among the stars, the Doppler shift due to a relative speed with respect to the observer, and the gravitational red-shift.

Not all stars are good approximations to black bodies, so that the black-body radiation law does not always accurately describe their colour. However, most stars are reasonable approximations of black bodies. The temperature of a star depends mainly on its size, its mass, its composition and its age, as astrophysicists are happy to explain. Orion is a good example of a coloured constellation: each star has a different colour. Long-exposure photographs beautifully show this.

Page 768
Ref. 497
Page 84

The basic colour determined by temperature is changed by two effects. The first, the *Doppler red-shift* z, depends on the speed v between source and observer as

Challenge 932 ny

$$z = \frac{\Delta\lambda}{\lambda} = \frac{f_S}{f_O} - 1 = \sqrt{\frac{c+v}{c-v}} - 1 \,. \tag{394}$$

Such shifts play a significant role only for remote, and thus faint, stars visible through the telescope. With the naked eye, Doppler shifts cannot be seen. But Doppler shifts can make distant stars shine in the infrared instead of in the visible domain. Indeed, the highest Doppler shifts observed for luminous objects are larger than 5.0, corresponding to a recessional speed of more than 94 % of the speed of light. Note that in the universe, the red-shift is also related to the scale factor $R(t)$ by

Challenge 933 ny

$$z = \frac{R(t_0)}{R(t_{\text{emission}})} - 1 \,. \tag{395}$$

Light at a red-shift of 5.0 was thus emitted when the universe was one sixth of its present age.

The other colour-changing effect, the *gravitational red-shift* z_g, depends on the matter density of the source and is given by

$$z_g = \frac{\Delta\lambda}{\lambda} = \frac{f_S}{f_0} - 1 = \frac{1}{\sqrt{1 - \frac{2GM}{c^2 R}}} - 1 \,. \tag{396}$$

It is usually quite a bit smaller than the Doppler shift. Can you confirm this?

Challenge 934 ny

No other red-shift processes are known; moreover, such processes would contradict all the known properties of nature. But the colour issue leads to the next question.

Page 603

TABLE 55 The colour of the stars

Class	Temperature	Example	Location	Colour
O	30 kK	Mintaka	δ Orionis	blue-violet
O	31(10) kK	Alnitak	ζ Orionis	blue-violet
B	22(6) kK	Bellatrix	γ Orionis	blue
B	26 kK	Saiph	κ Orionis	blue-white
B	12 kK	Rigel	β Orionis	blue-white
B	25 kK	Alnilam	ε Orionis	blue-white
B	17(5) kK	Regulus	α Leonis	blue-white
A	9.9 kK	Sirius	α Canis Majoris	blue-white
A	8.6 kK	Megrez	δ Ursae Majoris	white
A	7.6(2) kK	Altair	α Aquilae	yellow-white
F	7.4(7) kK	Canopus	α Carinae	yellow-white
F	6.6 kK	Procyon	α Canis Minoris	yellow-white
G	5.8 kK	Sun	ecliptic	yellow
K	3.5(4) kK	Aldebaran	α Tauri	orange
M	2.8(5) kK	Betelgeuse	α Orionis	red
D	<80 kK	–	–	any

Note. White dwarfs, or class-D stars, are remnants of imploded stars, with a size of only a few tens of kilometres. Not all are white; they can be yellow or red. They comprise 5% of all stars. None is visible with the naked eye. Temperature uncertainties in the last digit are given between parentheses.
The size of all other stars is an independent variable and is sometimes added as roman numerals at the end of the spectral type. (Sirius is an A1V star, Arcturus a K2III star.) Giants and supergiants exist in all classes from O to M.
To accommodate brown dwarfs, two new star classes, L and T, have been proposed.

Are there dark stars?

It could be that some stars are not seen because they are dark. This could be one explanation for the large amount of dark matter seen in the recent measurements of the background radiation. This issue is currently of great interest and hotly debated. It is known that objects more massive than Jupiter but less massive than the Sun can exist in states which emit hardly any light. They are called *brown dwarfs*. It is unclear at present how many such objects exist. Many of the so-called extrasolar 'planets' are probably brown dwarfs. The issue is not yet settled.

Page 604 Another possibility for dark stars are black holes. These are discussed in detail below.

Are all stars different? – Gravitational lenses

"Per aspera ad astra."*

* 'Through hardship to the stars.' A famous Latin motto. Often incorrectly given as 'per ardua at astra'.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

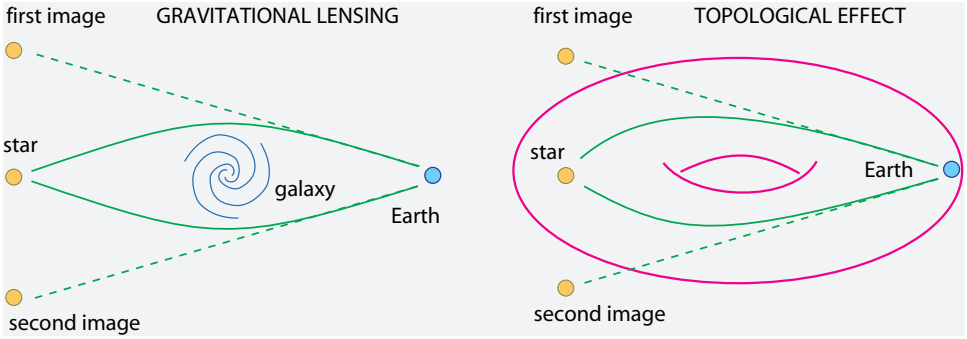

FIGURE 307 How one star can lead to several images

Are we sure that at night, two stars are really different? The answer is no. Recently, it was shown that two 'stars' were actually two images of the same object. This was found by comparing the flicker of the two images. It was found that the flicker of one image was exactly the same as the other, just shifted by 423 days. This result was found by the Estonian astrophysicist Jaan Pelt and his research group while observing two images of quasars in the system Q0957+561. Ref. 498

The two images are the result of *gravitational lensing*, as shown in Figure 307. Indeed, a large galaxy can be seen between the two images, much nearer to the Earth. This effect had been already considered by Einstein; however he did not believe that it was observable. The real father of gravitational lensing is Fritz Zwicky, who predicted in 1937 that the effect would be quite common and easy to observe, if lined-up galaxies instead of lined-up stars were considered, as indeed turned out to be the case. Ref. 499

Interestingly, when the time delay is known, astronomers are able to determine the size of the universe from this observation. Can you imagine how? Challenge 935 ny

In fact, if the two observed objects are lined up exactly behind each other, the more distant one is seen as *ring* around the nearer one. Such rings have indeed been observed, and the galaxy image around a central foreground galaxy at B1938+666, shown in Figure 308, is one of the most beautiful examples. In 2005, several cases of gravitational lensing by stars were also discovered. More interestingly, three events where one of the two stars has a Earth-mass planet have also been observed. The coming years will surely lead to many additional observations, helped by the sky observation programme in the southern hemisphere that checks the brightness of about 100 million stars every night.

Generally speaking, images of nearby stars are truly unique, but for the distant stars the problem is tricky. For single stars, the issue is not so important, seen overall. Reassuringly, only about 80 multiple star images have been identified so far. But when whole galaxies are seen as several images at once (and several dozens are known so far) we might start to get nervous. In the case of the galaxy cluster CL0024+1654, shown in Figure 309, seven thin, elongated, blue images of the same distant galaxy are seen around the yellow, nearer, elliptical galaxies.

But multiple images can be created not only by gravitational lenses; the *shape* of the universe could also play some tricks.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

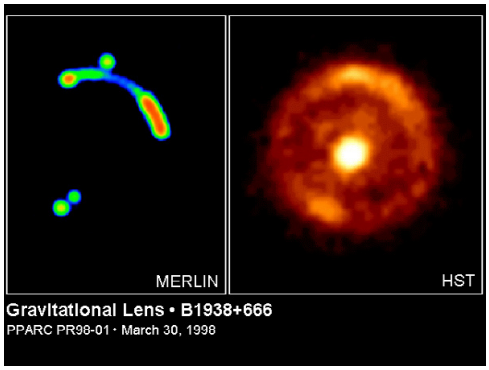

FIGURE 308 The Zwicky-Einstein ring B1938+666, seen in the radio spectrum (left) and in the optical domain (right) (NASA)

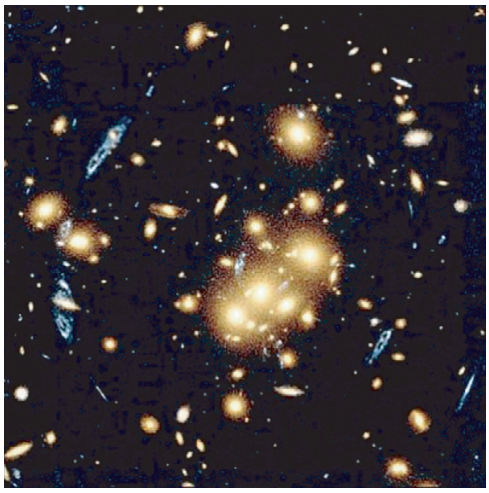

FIGURE 309 Multiple blue images of a galaxy formed by the yellow cluster CL0024+1654 (NASA)

What is the shape of the universe?

There is a popular analogy which avoids some of the just-mentioned problems. The universe in its evolution is similar to the surface of an ever-expanding sphere: the surface is finite, but it has no boundary. The universe simply has an additional dimension; therefore its volume is also ever increasing, finite, but without boundary. This statement presupposes that the universe has the same topology, the same 'shape' as that of a sphere with an additional dimension.

Ref. 500 But what is the experimental evidence for this statement? There is none. Nothing is yet known about the shape of the universe. It is extremely hard to determine it, simply because of its sheer size.

What do experiments say? In the nearby region of the universe, say within a few million light years, the topology is simply connected. But for large distances, almost nothing is certain. Maybe research into gamma-ray bursts will tell us something about the topol-

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ogy, as these bursts often originate from the dawn of time.* Maybe even the study of fluctuations of the cosmic background radiation can tell us something. All this research is still in its infancy.

Since little is known, we can ask about the range of possible answers. As just mentioned, in the standard model with $k = 1$, space-time is usually assumed to be a product of linear time, with the topology R of the real line, and a sphere S^3 for space. That is the simplest possible shape, corresponding to a *simply-connected* universe. For $k = 0$, the simplest topology of space is three-dimensional real space $\mathbb{R}^3$, and for $k = -1$ it is a hyperbolic manifold $\boldsymbol{H}^3$.

Page 582 In addition, Figure 302 showed that depending on the value of the cosmological constant, space could be finite and bounded, or infinite and unbounded. In Friedmann–Lemaître calculations, simple-connectedness is usually tacitly assumed, even though it is not at all required.

It could well be that space-time is *multiply* connected, like a higher-dimensional version of a torus. It could also have even more complex topologies.** In these cases, it could even be that the actual number of galaxies is much smaller than the observed number. This situation would correspond to a kaleidoscope, where a few beads produce a large number of images. In addition, topological surprises could also be hidden *behind* the horizon.

In fact, the range of possibilities is not limited to the simply and multiply connected cases suggested by classical physics. An additional and completely unexpected twist will appear in the last part of our walk, when quantum theory is included in the investigations. Page 1435

What is behind the horizon?

> The universe is a big place; perhaps the biggest.
> Kilgore Trout, *Venus on the Half Shell*.

The horizon is a tricky entity. In fact, all cosmological models show that it moves rapidly away from us. A detailed investigation shows that for a matter-dominated universe the horizon moves away from us with a velocity Ref. 502 Challenge 936 ny

$$v_{\text{horizon}} = 3c \,. \tag{397}$$

A pretty result, isn't it? Obviously, since the horizon does not transport any signal, this is not a contradiction of relativity. But what is behind the horizon?

If the universe is *open* or *marginal*, the matter we see at night is predicted by naively applied general relativity to be a – literally – infinitely small part of all matter existing. Indeed, an open or marginal universe implies that there is an infinite amount of matter behind the horizon. Is such a statement verifiable? Challenge 937 ny

* The story is told from the mathematical point of view by Bob Osserman, *Poetry of the Universe*, 1996.

** The Friedmann–Lemaître metric is also valid for any quotient of the just-mentioned simple topologies by a group of isometries, leading to dihedral spaces and lens spaces in the case $k = 1$, to tori in the case $k = 0$, and to *any* hyperbolic manifold in the case $k = -1$. Ref. 501

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In a *closed* universe, matter is still predicted to exist behind the horizon; however, in this case it is only a finite amount.

In short, the standard model of cosmology states that there is a lot of matter behind the horizon. Like most cosmologists, we sweep the issue under the rug and take it up only later in our walk. A precise description of the topic is provided by the hypothesis of inflation.

Why are there stars all over the place? – Inflation

What were the initial conditions of matter? Matter was distributed in a constant density over space expanding with great speed. How could this happen? The person who has explored this question most thoroughly is Alan Guth. So far, we have based our studies of the night sky, cosmology, on two observational principles: the isotropy and the homogeneity of the universe. In addition, the universe is (almost) flat. Inflation is an attempt to understand the origin of these observations. Flatness at the present instant of time is strange: the flat state is an unstable solution of the Friedmann equations. Since the universe is still flat after fourteen thousand million years, it must have been even flatter near the big bang.

Ref. 503 Guth argued that the precise flatness, the homogeneity and the isotropy could follow if in the first second of its history, the universe had gone through a short phase of exponential size increase, which he called *inflation*. This exponential size increase, by a factor of about 10^{26}, would homogenize the universe. This extremely short evolution would be driven by a still-unknown field, the *inflaton field*. Inflation also seems to describe correctly the growth of inhomogeneities in the cosmic background radiation.

However, so far, inflation poses as many questions as it solves. Twenty years after his initial proposal, Guth himself is sceptical on whether it is a conceptual step forward. The final word on the issue has not been said yet.

Why are there so few stars? – The energy and entropy content of the universe

> Die Energie der Welt ist constant. Die Entropie der Welt strebt einem Maximum zu.*
>
> Rudolph Clausius

The matter–energy density of the universe is near the critical one. Inflation, described in the previous section, is the favourite explanation for this connection. This implies that the actual number of stars is given by the behaviour of matter at extremely high temperatures, and by the energy density left over at lower temperature. The precise connection is still the topic of intense research. But this issue also raises a question about the quotation above. Was the creator of the term 'entropy', Rudolph Clausius, right when he made this famous statement? Let us have a look at what general relativity has to say about all this.

In general relativity, a *total* energy can indeed be defined, in contrast to *localized* energy, which cannot. The total energy of all matter and radiation is indeed a constant of motion.

* 'The energy of the universe is constant. Its entropy tends towards a maximum.'

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

It is given by the sum of the baryonic, luminous and neutrino parts:

$$E = E_b + E_\gamma + E_\nu \approx \frac{c^2 M_0}{T_0} + \ldots + \ldots \approx \frac{c^2}{G} + \ldots \,. \tag{398}$$

This value is constant only when integrated over the whole universe, not when just the inside of the horizon is taken.*

Many people also add a gravitational energy term. If one tries to do so, one is obliged to define it in such a way that it is exactly the negative of the previous term. This value for the gravitational energy leads to the popular speculation that the *total* energy of the universe might be zero. In other words, the number of stars could also be limited by this relation.

However, the discussion of *entropy* puts a strong question mark behind all these seemingly obvious statements. Many people have tried to give values for the entropy of the
Ref. 504 universe. Some have checked whether the relation

$$S = \frac{kc^3}{G\hbar}\frac{A}{4} = \frac{kG}{\hbar c} 4\pi M^2 \,, \tag{399}$$

Challenge 938 ny which is correct for black holes, also applies to the universe. This assumes that all the matter and all the radiation of the universe can be described by some average temperature. They argue that the entropy of the universe is surprisingly low, so that there must be some ordering principle behind it. Others even speculate over where the entropy of the universe comes from, and whether the horizon is the source for it.

But let us be careful. Clausius assumes, without the slightest doubt, that the universe is a closed system, and thus deduces the statement quoted above. Let us check this assumption. Entropy describes the maximum energy that can be extracted from a hot object. After the discovery of the particle structure of matter, it became clear that entropy is also given by the number of microstates that can make up a specific macrostate. But neither definition makes any sense if applied to the universe as a whole. There is no way to extract energy from it, and no way to say how many microstates of the universe would look like the macrostate.

The basic reason is the impossibility of applying the concept of *state* to the universe.
Page 34 We first defined the state as all those properties of a system which allow one to distinguish it from other systems with the same intrinsic properties, or which differ from one observer to another. You might want to check for yourself that for the universe, such state
Challenge 939 s properties do not exist at all.

We can speak of the state of space-time and we can speak of the state of matter and energy. But we cannot speak of the state of the universe, because the concept makes no sense. If there is no state of the universe, there is no entropy for it. And neither is there an energy value. This is in fact the only correct conclusion one can draw about the issue.

* Except for the case when pressure can be neglected.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Why is matter lumped?

We are able to see the stars because the universe consists mainly of empty space, in other words, because stars are small and far apart. But why is this the case? Cosmic expansion was deduced and calculated using a homogeneous mass distribution. So why did matter lump together?

It turns out that homogeneous mass distributions are *unstable*. If for any reason the density fluctuates, regions of higher density will attract more matter than regions of lower density. Gravitation will thus cause the denser regions to increase in density and the regions of lower density to be depleted. Can you confirm the instability, simply by assuming a space filled with dust and $a = GM/r^2$? In summary, even a tiny quantum fluctuation in the mass density will lead, after a certain time, to lumped matter.

Challenge 940 ny

But how did the first inhomogeneities form? That is one of the big problems of modern physics and astrophysics, and there is no accepted answer yet. Several modern experiments are measuring the variations of the cosmic background radiation spectrum with angular position and with polarization; these results, which will be available in the coming years, might provide some information on the way to settle the issue.

Ref. 505

Why are stars so small compared with the universe?

Given that the matter density is around the critical one, the size of stars, which contain most of the matter, is a result of the interaction of the elementary particles composing them. Below we will show that general relativity (alone) cannot explain any size appearing in nature. The discussion of this issue is a theme of quantum theory.

Page 620

Are stars and galaxies moving apart or is the universe expanding?

Can we distinguish between space expanding and galaxies moving apart? Yes, we can. Can you find an argument or devise an experiment to do so?

Challenge 941 ny

The expansion of the universe does not apply to the space on the Earth. The expansion is calculated for a homogeneous and isotropic mass distribution. Matter is neither homogeneous nor isotropic inside the galaxy; the approximation of the cosmological principle is not valid down here. It has even been checked experimentally, by studying atomic spectra in various places in the solar system, that there is *no* Hubble expansion taking place around us.

Ref. 506

Is there more than one universe?

The existence of 'several' universes might be an option when we study the question whether we see all the stars. But you can check that neither definition of 'universe' given above, be it 'all matter-energy' or 'all matter–energy and all space-time', allows us to answer the question positively.

Challenge 942 ny

There is no way to define a plural for universe: either the universe is everything, and then it is unique, or it is not everything, and then it is not the universe. We will discover that quantum theory does not change this conclusion, despite recurring reports to the contrary.

Page 1094

Whoever speaks of many universes is talking gibberish.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Why are the stars fixed? – Arms, stars and Mach's principle

> Si les astres étaient immobiles, le temps et l'espace n'existeraient plus.*
>
> Maurice Maeterlink.

The two arms possessed by humans have played an important role in discussions about motion, and especially in the development of relativity. Looking at the stars at night, we can make a simple observation, if we keep our arms relaxed. Standing still, our arms hang down. Then we turn rapidly. Our arms lift up. In fact they do so whenever we see the stars turning. Some people have spent a large part of their lives studying this phenomenon. Why?

Ref. 507 Stars and arms prove that motion is relative, not absolute.** This observation leads to two possible formulations of what Einstein called *Mach's principle*.

— *Inertial frames are determined by the rest of the matter in the universe.*

This idea is indeed realized in general relativity. No question about it.

— *Inertia is due to the* interaction *with the rest of the universe.*

This formulation is more controversial. Many interpret it as meaning that the *mass* of an object depends on the distribution of mass in the rest of the universe. That would mean that one needs to investigate whether mass is anisotropic when a large body is nearby. Of course, this question has been studied experimentally; one simply needs to measure whether a particle has the same mass values when accelerated in different directions. Ref. 508 Unsurprisingly, to a high degree of precision, no such anisotropy has been found. Many therefore conclude that Mach's principle is wrong. Others conclude with some pain in Ref. 509 their stomach that the whole topic is not yet settled.

But in fact it is easy to see that Mach *cannot* have meant a mass variation at all: one then would also have to conclude that mass is distance-dependent, even in Galilean physics. But this is known to be false; nobody in his right mind has ever had any doubts Challenge 943 e about it.

The whole debate is due to a misunderstanding of what is meant by 'inertia': one can interpret it as inertial *mass* or as inertial *motion* (like the moving arms under the stars). There is no evidence that Mach believed either in anisotropic mass or in distance-dependent mass; the whole discussion is an example people taking pride in not making a mistake which is incorrectly imputed to another, supposedly more stupid, person.***

Obviously, inertial effects do depend on the distribution of mass in the rest of the universe. Mach's principle is correct. Mach made some blunders in his life (he is infamous for opposing the idea of atoms until he died, against experimental evidence) but

* 'If the stars were immobile, time and space would not exist any more.' Maurice Maeterlink (1862–1949) is a famous Belgian dramatist.

** The original reasoning by Newton and many others used a bucket and the surface of the water in it; but the arguments are the same.

*** For another example, at school one usually hears that Columbus was derided because he thought the Earth to be spherical. But he was not derided at all for this reason; there were only disagreements on the *size* of the Earth, and in fact it turned out that his critics were right, and that he was wrong in his own, much too small, estimate of the radius.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

his principle is *not* one of them. Unfortunately it is to be expected that the myth about the incorrectness of Mach's principle will persist, like that of the derision of Columbus. Ref. 509

In fact, Mach's principle is valuable. As an example, take our galaxy. Experiments show that it is flattened and rotating. The Sun turns around its centre in about 250 million years. Indeed, if the Sun did not turn around the galaxy's centre, we would fall into it in about 20 million years. As the physicist Dennis Sciama pointed out, from the shape of our galaxy we can draw a powerful conclusion: there must be a lot of other matter, i.e., a lot of other stars and galaxies in the universe. Can you confirm his reasoning? Challenge 944 s

At rest in the universe

There is no preferred frame in special relativity, no absolute space. Is the same true in the actual universe? No; there *is* a preferred frame. Indeed, in the standard big-bang cosmology, the average galaxy is at rest. Even though we talk about the big bang, any average galaxy can rightly maintain that it is at rest. Each one is in free fall. An even better realization of this privileged frame of reference is provided by the background radiation.

In other words, the night sky is black because we move with almost no speed through background radiation. If the Earth had a large velocity relative to the background radiation, the sky would be bright even at night, thanks to the Doppler effect for the background radiation. In other words, the fact that the night sky is dark in all directions is a consequence of our slow motion against the background radiation.

This 'slow' motion has a speed of 368 km/s. (This is the value of the motion of the Sun; there are variations due to addition of the motion of the Earth.) The speed value is large in comparison to everyday life, but small compared to the speed of light. More detailed studies do not change this conclusion. Even the motion of the Milky Way and that of the local group against the cosmic background radiation is of the order of 600 km/s; that is still much slower than the speed of light. The reasons why the galaxy and the solar system move with these 'low' speeds across the universe have already been studied in our walk. Can you give a summary? Challenge 945 ny

By the way, is the term 'universe' correct? Does the universe rotate, as its name implies? If by universe one means the whole of experience, the question does not make sense, because rotation is only defined for bodies, i.e., for parts of the universe. However, if by universe one only means 'all matter', the answer *can* be determined by experiments. Ref. 510 It turns out that the rotation is extremely small, if there is any: measurements of the cosmic background radiation show that in the lifetime of the universe, it cannot have rotated by more than a hundredth of a millionth of a turn! In short, 'universe' is a misnomer.

Does light attract light?

Another reason why we can see stars is that their light reaches us. But why are travelling light rays not disturbed by each other's gravitation? We know that light is energy and that any energy attracts other energy through gravitation. In particular, light is electromagnetic energy, and experiments have shown that all electromagnetic energy is subject to gravitation. Could two light beams that are advancing with a small angle between them converge, because of mutual gravitational attraction? That could have measurable and possibly interesting effects on the light observed from distant stars.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

The simplest way to explore the issue is to study the following question: Do parallel light beams remain parallel? Interestingly, a precise calculation shows that mutual gravitation does *not* alter the path of two parallel light beams, even though it *does* alter the path of antiparallel light beams.* The reason is that for parallel beams moving at light speed, the gravitomagnetic component exactly *cancels* the gravitoelectric component.

Ref. 511

Challenge 946 ny

Since light does not attract light moving along, light is not disturbed by its own gravity during the millions of years that it takes to reach us from distant stars. Light does not attract or disturb light moving alongside. So far, all known quantum-mechanical effects also confirm this conclusion.

Does light decay?

In the section on quantum theory we will encounter experiments showing that light is made of particles. It is plausible that these photons might *decay* into some other particle, as yet unknown, or into lower-frequency photons. If that actually happened, we would not be able to see distant stars.

But any decay would also mean that light would change its direction (why?) and thus produce blurred images for remote objects. However, no blurring is observed. In addition, the Soviet physicist Matvey Bronstein demonstrated in the 1930s that any light decay process would have a larger rate for smaller frequencies. When people checked the shift of radio waves, in particular the famous 21 cm line, and compared it with the shift of light from the same source, no difference was found for any of the galaxies tested.

Challenge 947 ny

Ref. 512

People even checked that Sommerfeld's fine-structure constant, which determines the colour of objects, does not change over time. Despite an erroneous claim in recent years, no change could be detected over thousands of millions of years.

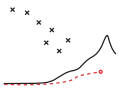
Ref. 513

Of course, instead of decaying, light could also be *hit* by some hitherto unknown entity. But this possibility is excluded by the same arguments. These investigations also show that there is no additional red-shift mechanism in nature apart from the Doppler and gravitational red-shifts.

Challenge 948 ny

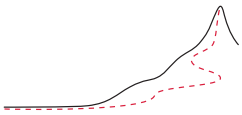
Page 593

The visibility of the stars at night has indeed shed light on numerous properties of nature. We now continue our mountain ascent with a more general issue, nearer to our quest for the fundamentals of motion.



* Antiparallel beams are parallel beams travelling in opposite directions.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 20

BLACK HOLES – FALLING FOREVER

> Qui iacet in terra non habet unde cadat.*
>
> Alanus de Insulis

Why study black holes?

Black holes are the most extreme gravitational phenomena. They realize nature's limit of length-to-mass ratios. They produce the highest force value possible in nature; as a result, they produce high space-time curvatures. Therefore, black holes cannot be studied *without* general relativity. In addition, the study of black holes is a major stepping stone towards unification and the final description of motion.

Ref. 406 'Black hole' is shorthand for 'gravitationally completely collapsed object'. For many years it was unclear whether or not they exist. But the available experimental data have now led most experts to conclude that there is a black hole at the centre of most galaxies, Ref. 514 including our own. Black holes are also suspected at the heart of quasars and of gamma ray bursters. It seems that the evolution of galaxies is strongly tied to the evolution of black holes. In addition, half a dozen smaller black holes have been identified elsewhere in our galaxy. For these and many other reasons, black holes, the most impressive, the Ref. 515 most powerful and the most relativistic systems in nature, are a fascinating subject of study.

Horizons

The escape velocity is the speed needed to launch an projectile in such a way that it never falls back down. The escape velocity depends on the mass and the size of the planet from which the launch takes place. What happens when a planet or star has an escape velocity that is larger than the speed of light c? Such objects were first imagined by the British geologist John Michell in 1784, and independently by the French mathematician Pierre Ref. 516 Laplace in 1795, long before general relativity was developed. Michell and Laplace realized something fundamental: even if an object with such a high escape velocity were a hot star, it would appear to be completely *black*. The object would not allow any light to leave it; in addition, it would block all light coming from behind it. In 1967, John Wheeler**

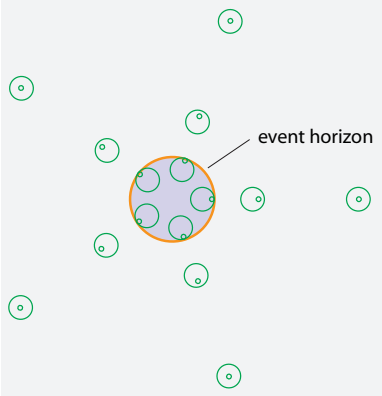

FIGURE 310 The light cones in the equatorial plane around a non-rotating black hole, seen from above

Ref. 406 coined the now standard term *black hole*.

It only takes a short calculation to show that light cannot escape from a body of mass Challenge 949 ny M whenever the radius is smaller than a critical value given by

$$R_S = \frac{2GM}{c^2} \tag{400}$$

called the *Schwarzschild radius*. The formula is valid both in universal gravity and in general relativity, provided that in general relativity we take the radius as meaning the circumference divided by 2π. Such a body realizes the limit value for length-to-mass ratios in nature. For this and other reasons to be given shortly, we will call R_S also the *size* of the black hole of mass M. (But note that it is only half the diameter. In addition, the term 'size' has to be taken with some grain of salt.) In principle, it is possible to imagine an object with a smaller length-to-mass ratio; but nobody has yet observed one. In fact, we will discover that there is no way to observe an object smaller than the Schwarzschild radius, just as an object moving faster than the speed of light cannot be observed. However, we can observe black holes – the limit case – just as we can observe entities moving at the speed of light.

When a test mass approaches the critical radius R_S, two things happen. First, the local proper acceleration for (imaginary) point masses increases without bound. For realistic objects of finite size, the black hole realizes the highest force possible in nature. Something that falls into a black hole cannot be pulled back out. A black hole thus swallows all matter that falls into it. It acts like a cosmic vacuum cleaner.

At the surface of a black hole, the red-shift factor for a distant observer also increases without bound. The ratio between the two quantities is called the *surface gravity* of a Challenge 950 ny black hole. It is given by

$$g_{\text{surf}} = \frac{GM}{R_S^2} = \frac{c^4}{4GM} = \frac{c^2}{2R_S} \,. \tag{401}$$

A black hole thus does not allow any light to leave it.

passion and in detail, but without any mathematics.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

A surface that realizes the force limit and an infinite red-shift makes it is impossible to send light, matter, energy or signals of any kind to the outside world. A black hole is thus surrounded by a horizon. We know that a horizon is a limit surface. In fact, a horizon is a limit in two ways. First, a horizon is a limit to communication: nothing can communicate across it. Secondly, a horizon is a surface of maximum force and power. These properties are sufficient to answer all questions about the effects of horizons. For example: What happens when a light beam is sent upwards from the horizon? And from slightly above the horizon?

Challenge 951 ny

Black holes, regarded as astronomical objects, are thus different from planets. During the formation of planets, matter lumps together; as soon as it cannot be compressed any further, an equilibrium is reached, which determines the radius of the planet. That is the same mechanism as when a stone is thrown towards the Earth: it stops falling when it *hits* the ground. A 'ground' is formed whenever matter hits other matter. In the case of a black hole, there is no ground; everything *continues* falling. That is why, in Russian, black holes used to be called *collapsars*.

This continuous falling takes place when the concentration of matter is so high that it overcomes all those interactions which make matter *impenetrable* in daily life. In 1939, Robert Oppenheimer* and Hartland Snyder showed theoretically that a black hole forms whenever a star of sufficient mass stops burning. When a star of sufficient mass stops burning, the interactions that form the 'floor' disappear, and everything continues falling without end.

Ref. 517

A *black hole is matter in permanent free fall.* Nevertheless, its radius for an outside observer remains constant! But that is not all. Furthermore, because of this permanent free fall, black holes are the only state of matter in thermodynamic equilibrium! In a sense, floors and all other every-day states of matter are metastable: these forms are not as stable as black holes.

The characterizing property of a black hole is thus its *horizon*. The first time we encountered horizons was in special relativity, in the section on accelerated observers. The horizons due to gravitation are similar in all their properties; the section on the maximum force and power gave a first impression. The only difference we have found is due to the neglect of gravitation in special relativity. As a result, horizons in nature cannot be planar, in contrast to what is suggested by the observations of the imagined point-like observers assumed to exist in special relativity.

Page 464

Both the maximum force principle and the field equations imply that the space-time around a rotationally symmetric (thus non-rotating) and electrically neutral mass is described by

Page 506

$$\mathrm{d}i^2 = \left(1 - \frac{2GM}{rc^2}\right)\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{1 - \frac{2GM}{rc^2}} - r^2\mathrm{d}\varphi^2/c^2 \,. \tag{402}$$

This is the so-called *Schwarzschild metric*. As mentioned above, r is the circumference divided by 2π; t is the time measured at infinity. No *outside* observer will ever receive

* Robert Oppenheimer (1904–1967), important US-American physicist. He can be called the father of theoretical physics in the USA. He worked on quantum theory and atomic physics. He then headed the team that developed the nuclear bomb during the Second World War. He was also the most prominent (innocent) victim of one of the greatest witch-hunts ever organized in his home country. See also the www.nap.edu/readingroom/books/biomems/joppenheimer.html website.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

any signal emitted from a radius value $r = 2GM/c^2$ or smaller. Indeed, as the proper time i of an observer at radius r is related to the time t of an observer at infinity through

$$\mathrm{d}i = \sqrt{1 - \frac{2GM}{rc^2}}\,\mathrm{d}t\,, \tag{403}$$

we find that an observer at the horizon would have vanishing proper time. In other words, at the horizon the red-shift is infinite. (In fact, the surface of infinite red-shift and the horizon coincide only for non-rotating black holes. For rotating black holes, the two surfaces are distinct.) Everything happening at the horizon goes on infinitely slowly, as observed by a distant observer. In other words, for a distant observer observing what is going on at the horizon itself, nothing at all ever happens.

In the same way that observers cannot reach the speed of light, observers cannot reach a horizon. For a second observer, it can only happen that the first is moving almost as fast as light; in the same way, for a second observer, it can only happen that the first has almost reached the horizon. In addition, a traveller cannot feel how much he is near the speed of light for another, and experiences light speed as unattainable; in the same way, a traveller (into a large black hole) cannot feel how much he is near a horizon and experiences the horizon as unattainable.

In general relativity, horizons of any kind are predicted to be *black*. Since light cannot escape from them, classical horizons are completely dark surfaces. In fact, horizons are the darkest entities imaginable: nothing in nature is darker. Nonetheless, we will later discover that physical horizons are not completely black.

Orbits

Ref. 512 Since black holes curve space-time strongly, a body moving near a black hole behaves in more complicated ways than predicted by universal gravity. In universal gravity, paths are either ellipses, parabolas, or hyperbolas; all these are plane curves. It turns out that paths lie in a plane only near *non-rotating* black holes.*

Challenge 953 ny Around non-rotating black holes, also called *Schwarzschild black holes*, circular paths are impossible for radii less than $3R_S/2$ (can you show why?) and are unstable to perturbations from there up to a radius of $3R_S$. Only at larger radii are circular orbits stable. Around black holes, there are no elliptic paths; the corresponding rosetta path is shown in Figure 311. Such a path shows the famous periastron shift in all its glory.

Challenge 954 ny Note that the potential around a black hole is not appreciably different from $1/r$ for distances above about fifteen Schwarzschild radii. For a black hole of the mass of the Sun, that would be 42 km from its centre; therefore, we would not be able to note any difference for the path of the Earth around the Sun.

We have mentioned several times in our adventure that gravitation is characterized by its tidal effects. Black holes show extreme properties in this respect. If a cloud of dust

* For such paths, Kepler's rule connecting the average distance and the time of orbit

$$\frac{GMt^3}{(2\pi)^2} = r^3 \tag{404}$$

Challenge 952 ny still holds, provided the proper time and the radius measured by a distant observer are used.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

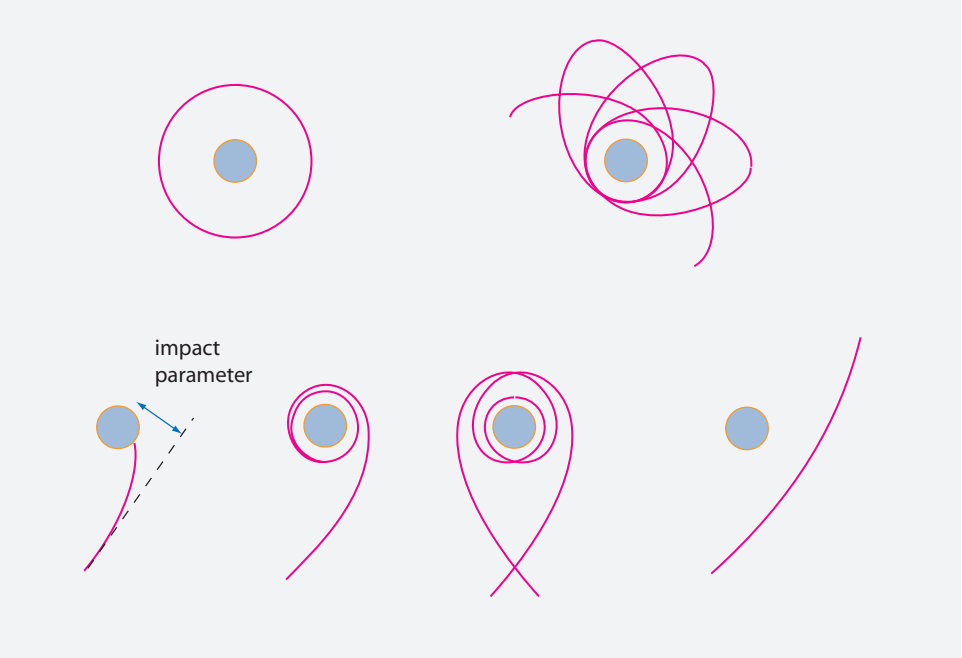

FIGURE 311 Motions of uncharged objects around a non-rotating black hole – for different impact parameters and initial velocities

falls into a black hole, the size of the cloud increases as it falls, until the cloud envelops the whole horizon. In fact, the result is valid for any extended body. This property of black holes will be of importance later on, when we will discuss the size of elementary particles.

For falling bodies coming from infinity, the situation near black holes is even more interesting. Of course there are no hyperbolic paths, only trajectories similar to hyperbolas for bodies passing far enough away. But for small, but not too small impact parameters, a body will make a number of turns around the black hole, before leaving again. The number of turns increases beyond all bounds with decreasing impact parameter, until a value is reached at which the body is captured into an orbit at a radius of $2R$, as shown in Figure 311. In other words, this orbit *captures* incoming bodies if they approach it below a certain critical angle. For comparison, remember that in universal gravity, capture is never possible. At still smaller impact parameters, the black hole swallows the incoming mass. In both cases, capture and deflection, a body can make several turns around the black hole, whereas in universal gravity it is impossible to make more than *half* a turn around a body.

Challenge 955 ny

The most absurd-looking orbits, though, are those corresponding to the parabolic case of universal gravity. (These are of purely academic interest, as they occur with probability zero.) In summary, relativity changes the motions due to gravity quite drastically.

Around *rotating* black holes, the orbits of point masses are even more complex than those shown in Figure 311; for bound motion, for example, the ellipses do not stay in one plane – thanks to the Thirring–Lense effect – leading to extremely involved orbits in

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

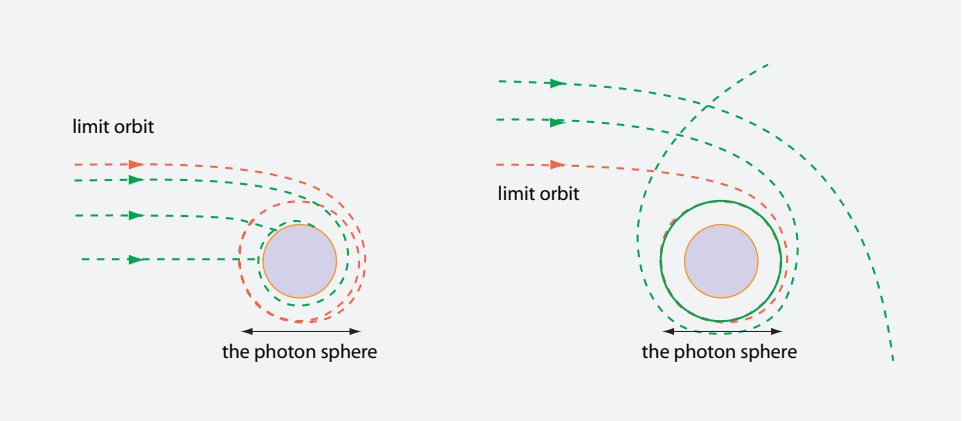

FIGURE 312 Motions of *light* passing near a non-rotating black hole

three dimensions filling the space around the black hole.

For *light* passing a black hole, the paths are equally interesting, as shown in Figure 312. There are no qualitative differences with the case of rapid particles. For a non-rotating black hole, the path obviously lies in a single plane. Of course, if light passes sufficiently nearby, it can be strongly bent, as well as captured. Again, light can also make one or several turns around the black hole before leaving or being captured. The limit between the two cases is the path in which light moves in a circle around a black hole, at $3R/2$. If we were located on that orbit, we would see the back of our head by looking forward!

Challenge 956 ny However, this orbit is unstable. The surface containing all orbits inside the circular one is called the *photon sphere*. The photon sphere thus divides paths leading to capture from those leading to infinity. Note that there is no *stable* orbit for light around a black hole.

Challenge 957 ny Are there any rosetta paths for light around a black hole?

For light around a *rotating* black hole, paths are much more complex. Already in the equatorial plane there are two possible circular light paths: a smaller one in the direction

Challenge 958 ny of the rotation, and a larger one in the opposite direction.

For *charged* black holes, the orbits for falling charged particles are even more complex. The electrical field lines need to be taken into account. Several fascinating effects appear which have no correspondence in usual electromagnetism, such as effects similar to electrical versions of the Meissner effect. The behaviour of such orbits is still an active area of research in general relativity.

Hair and entropy

How is a black hole characterized? It turns out that all properties of black holes follow from a few basic quantities characterizing them, namely their mass M, their angular momentum J, and their electric charge Q.* All other properties – such as size, shape, colour,

* The existence of three basic characteristics is reminiscent of particles. We will find out more about the connection between black holes and particles in the final part of our mountain ascent.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

magnetic field – are uniquely determined by these.* It is as though, to use Wheeler's colourful analogy, one could deduce every characteristic of a woman from her size, her waist and her height. Physicists also say that black holes 'have no hair,' meaning that (classical) black holes have no other degrees of freedom. This expression was also introduced by Wheeler.** This fact was proved by Israel, Carter, Robinson and Mazur; they showed that for a given mass, angular momentum and charge, there is only *one* possible black hole. (However, the uniqueness theorem is not valid any more if the black hole carries nuclear quantum numbers, such as weak or strong charges.)

Ref. 520

Ref. 521

In other words, a black hole is independent of how it has formed, and of the materials used when forming it. Black holes all have the same composition, or better, they have no composition at all (at least classically).

The mass M of a black hole is not restricted by general relativity. It may be as small as that of a microscopic particle and as large as many million solar masses. But for their angular momentum J and electric charge Q, the situation is different. A rotating black hole has a maximum possible angular momentum and a maximum possible electric (and magnetic) charge.*** The limit on the angular momentum appears because its perimeter may not move faster than light. The electric charge is also limited. The two limits are not independent: they are related by

Challenge 959 ny

$$\left(\frac{J}{cM}\right)^2 + \frac{GQ^2}{4\pi\varepsilon_0 c^4} \leqslant \left(\frac{GM}{c^2}\right)^2 \quad . \tag{405}$$

This follows from the limit on length-to-mass ratios at the basis of general relativity. Rotating black holes realizing the limit (405) are called *extremal* black holes. The limit (405) implies that the horizon radius of a general black hole is given by

Challenge 960 ny

$$r_\mathrm{h} = \frac{GM}{c^2}\left(1 + \sqrt{1 - \frac{J^2c^2}{M^4G^2} - \frac{Q^2}{4\pi\varepsilon_0 GM^2}}\right) \tag{406}$$

For example, for a black hole with the mass and half the angular momentum of the Sun, namely $2 \cdot 10^{30}$ kg and $0.45 \cdot 10^{42}\,\mathrm{kg\,m^2/s}$, the charge limit is about $1.4 \cdot 10^{20}$ C.

How does one distinguish rotating from non-rotating black holes? First of all by the *shape*. Non-rotating black holes must be spherical (any non-sphericity is radiated away as gravitational waves) and rotating black holes have a slightly flattened shape, uniquely determined by their angular momentum. Because of their rotation, their surface of infinite

Ref. 522

* Mainly for marketing reasons, non-rotating and electrically neutral black holes are often called *Schwarzschild* black holes; uncharged and rotating ones are often called *Kerr* black holes, after Roy Kerr, who discovered the corresponding solution of Einstein's field equations in 1963. Electrically charged but non-rotating black holes are often called *Reissner–Nordström black holes*, after the German physicist Hans Reissner and the Finnish physicist Gunnar Nordström. The general case, charged and rotating, is sometimes named after Kerr and Newman.

Ref. 518

Ref. 519

** Wheeler claims that he was inspired by the difficulty of distinguishing between bald men; however, Feynman, Ruffini and others had a clear anatomical image in mind when they stated that 'black holes, in contrast to their surroundings, have no hair.'

Ref. 406

*** More about the still hypothetical magnetic charge later on. In black holes, it enters like an additional type of charge into all expressions in which electric charge appears.

Page 693

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

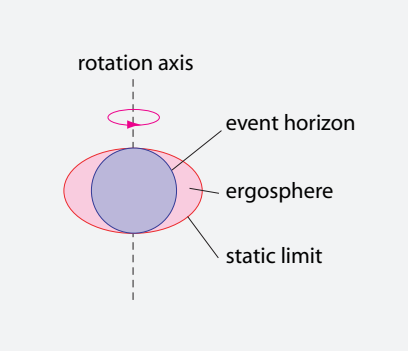

FIGURE 313 The ergosphere of a rotating black hole

gravity or infinite red-shift, called the *static limit*, is different from their (outer) horizon. The region in between is called the *ergosphere*; this is a misnomer as it is *not* a sphere. (It is so called because, as we will see shortly, it can be used to extract energy from the black hole.) The motion of bodies within the ergosphere can be quite complex. It suffices to mention that rotating black holes drag any in-falling body into an orbit around them; this is in contrast to non-rotating black holes, which swallow in-falling bodies. In other words, rotating black holes are not really 'holes' at all, but rather vortices.

The distinction between rotating and non-rotating black holes also appears in the horizon surface area. The (horizon) surface area A of a non-rotating and uncharged black hole is obviously related to its mass M by

Challenge 961 e

$$A = \frac{16\pi G^2}{c^4} M^2 \,. \tag{407}$$

The relation between surface area and mass for a rotating and charged black hole is more complex: it is given by

$$A = \frac{8\pi G^2}{c^4} M^2 \left(1 + \sqrt{1 - \frac{J^2 c^2}{M^4 G^2} - \frac{Q^2}{4\pi\varepsilon_0 G M^2}}\right) \tag{408}$$

where J is the angular momentum and Q the charge. In fact, the relation

$$A = \frac{8\pi G}{c^2} M r_\mathrm{h} \tag{409}$$

is valid for *all* black holes. Obviously, in the case of an electrically charged black hole, the rotation also produces a magnetic field around it. This is in contrast with non-rotating black holes, which cannot have a magnetic field.

Black holes as energy sources

Can one extract energy from a black hole? Roger Penrose has discovered that this is possible for *rotating* black holes. A rocket orbiting a rotating black hole in its ergosphere

Ref. 523

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

could switch its engines on and would then get hurled into outer space at tremendous velocity, much greater than what the engines could have produced by themselves. In fact, the same effect is used by rockets on the Earth, and is the reason why all satellites orbit the Earth in the same direction; it would require much more fuel to make them turn the other way.*

The energy gained by the rocket would be lost by the black hole, which would thus slow down and lose some mass; on the other hand, there is a mass increases due to the exhaust gases falling into the black hole. This increase always is larger than, or at best equal to, the loss due to rotation slowdown. The best one can do is to turn the engines on exactly at the horizon; then the horizon area of the black hole stays constant, and only its rotation is slowed down.**

As a result, for a neutral black hole *rotating* with its maximum possible angular momentum, $1 - 1/\sqrt{2} = 29.3\,\%$ of its total energy can be extracted through the Penrose process. For black holes rotating more slowly, the percentage is obviously smaller.

Challenge 963 ny

For *charged* black holes, such irreversible energy extraction processes are also possible. Can you think of a way? Using expression (405), we find that up to 50 % of the mass of a non-rotating black hole can be due to its charge. In fact, in the quantum part of our mountain ascent we will encounter an energy extraction process which nature seems to use quite frequently.

Challenge 964 ny

Challenge 965 ny

Page 1211

The Penrose process allows one to determine how angular momentum and charge increase the mass of a black hole. The result is the famous mass–energy relation

Ref. 524

$$M^2 = \frac{E^2}{c^4} = \left(m_{\text{irr}} + \frac{Q^2}{16\pi\varepsilon_0 G m_{\text{irr}}}\right)^2 + \frac{J^2}{4m_{\text{irr}}^2}\frac{c^2}{G^2} = \left(m_{\text{irr}} + \frac{Q^2}{8\pi\varepsilon_0 \rho_{\text{irr}}}\right)^2 + \frac{J^2}{\rho_{\text{irr}}^2}\frac{1}{c^2} \tag{410}$$

which shows how the electrostatic and the rotational energy enter the mass of a black hole. In the expression, m_{irr} is the *irreducible mass* defined as

$$m_{\text{irr}}^2 = \frac{A(M, Q = 0, J = 0)}{16\pi}\frac{c^4}{G^2} = \left(\rho_{\text{irr}}\frac{c^2}{2G}\right)^2 \tag{411}$$

and ρ_{irr} is the *irreducible radius*.

Detailed investigations show that there is no process which *decreases* the horizon area, and thus the irreducible mass or radius, of the black hole. People have checked this in all ways possible and imaginable. For example, when two black holes merge, the total area increases. One calls processes which keep the area and energy of the black hole constant *reversible*, and all others irreversible. In fact, the area of black holes behaves like the *entropy* of a closed system: it never decreases. That the area in fact *is* an entropy was first stated in 1970 by Jacob Bekenstein. He deduced that only when an entropy is

Ref. 525

* And it would be much more dangerous, since any small object would hit such an against-the-stream satellite at about 15.8 km/s, thus transforming the object into a dangerous projectile. In fact, any power wanting to destroy satellites of the enemy would simply have to load a satellite with nuts or bolts, send it into space the wrong way, and distribute the bolts into a cloud. It would make satellites impossible for many decades to come.

Challenge 962 ny

** It is also possible to extract energy from rotational black holes through gravitational radiation.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

ascribed to a black hole, is it possible to understand where the entropy of all the material falling into it is collected.

The black hole entropy is a function only of the mass, the angular momentum and the charge of the black hole. You might want to confirm Bekenstein's deduction that the
Challenge 966 ny entropy S is proportional to the horizon area. Later it was found, using quantum theory, that

$$S = \frac{A}{4}\frac{kc^3}{\hbar G} = \frac{A\,k}{4\,l_{\mathrm{Pl}}^2} \,. \tag{412}$$

This famous relation cannot be deduced without quantum theory, as the absolute value of entropy, as for any other observable, is never fixed by classical physics alone. We will
Page 1213 discuss this expression later on in our mountain ascent.

If black holes have an entropy, they also must have a temperature. If they have a temperature, they must shine. Black holes thus cannot be black! This was proven by Stephen Hawking in 1974 with extremely involved calculations. However, it could have been de-
Page 1208 duced in the 1930s, with a simple Gedanken experiment which we will present later on. You might want to think about the issue, asking and investigating what strange consequences would appear if black holes had no entropy. Black hole radiation is a further, though tiny (quantum) mechanism for energy extraction, and is applicable even to non-
Page 1208 rotating, uncharged black holes. The interesting connections between black holes, thermodynamics, and quantum theory will be presented in the upcoming parts of our mountain ascent. Can you imagine other mechanisms that make black holes shine?
Challenge 967 ny

Curiosities and fun challenges about black holes

> Tiens, les trous noirs. C'est troublant.*
>
> Anonymous

Black holes have many counter-intuitive properties. We will first have a look at the clas-
Page 1216 sical effects, leaving the quantum effects for later on.

* *

Following universal gravity, light could climb upwards from the surface of a black hole and then fall back down. In general relativity, a black hole does not allow light to climb
Challenge 968 ny up at all; it can only fall. Can you confirm this?

* *

What happens to a person falling into a black hole? An outside observer gives a clear answer: the falling person *never* arrives there since she needs an infinite time to reach the
Challenge 969 ny horizon. Can you confirm this result? The falling person, however, reaches the horizon
Challenge 970 ny in a *finite* amount of her own time. Can you calculate it?

This result is surprising, as it means that for an outside observer in a universe with *finite* age, black holes cannot have formed yet! At best, we can only observe systems that are busy forming black holes. In a sense, it might be correct to say that black holes do not exist. Black holes could have existed right from the start in the fabric of space-time. On

* No translation possible.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

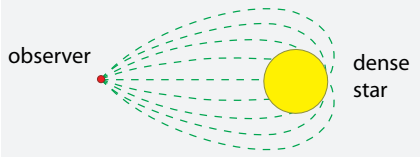

FIGURE 314 Motion of some light rays from a dense body to an observer

the other hand, we will find out later why this is impossible. In short, it is important to keep in mind that the idea of black hole is a limit concept but that usually, limit concepts (like baths or temperature) are useful descriptions of nature. Independently of this last issue, we can confirm that in nature, the length-to-mass ratio always satisfies

$$\frac{L}{M} \geqslant \frac{4G}{c^2} \,. \tag{413}$$

* *

Interestingly, the *size* of a person falling into a black hole is experienced in vastly different ways by the falling person and a person staying outside. If the black hole is large, the infalling observer feels almost nothing, as the tidal effects are small. The outside observer makes a startling observation: he sees the falling person *spread* all over the horizon of the black hole. *In-falling, extended bodies cover the whole horizon.* Can you explain this fact, for example by using the limit on length-to-mass ratios?

Challenge 971 ny

This strange result will be of importance later on in our exploration, and lead to important results about the size of point particles.

* *

An observer near a (non-rotating) black hole, or in fact near any object smaller than 7/4 times its gravitational radius, can even see the complete *back* side of the object, as shown in Figure 314. Can you imagine what the image looks like? Note that in addition to the paths shown in Figure 314, light can also turn several times around the black hole before reaching the observer! Therefore, such an observer sees an infinite number of images of the black hole. The resulting formula for the angular size of the innermost image was given above.

Challenge 972 ny

Page 517

In fact, the effect of gravity means that it is possible to observe more than half the surface of *any* spherical object. In everyday life, however, the effect is small: for example, light bending allows us to see about 50.0002 % of the surface of the Sun.

* *

A mass point inside the smallest circular path of light around a black hole, at $3R/2$, cannot stay in a circle, because in that region, something strange happens. A body which circles another in everyday life always feels a tendency to be pushed outwards; this centrifugal effect is due to the inertia of the body. But at values below $3R/2$, a circulating body is pushed *inwards* by its inertia. There are several ways to explain this paradoxical effect. The simplest is to note that near a black hole, the weight increases faster than the centrifugal force, as you may want to check yourself. Only a rocket with engines switched on and pushing towards the sky can orbit a black hole at $3R/2$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

By the way, how can gravity, or an electrical field, come out of a black hole, if no signal and no energy can leave it? Challenge 974 s

* *

Do *white holes* exist, i.e., time-inverted black holes, in which everything flows out of, instead of into, some bounded region? Challenge 975 ny

* *

Challenge 976 ny Show that a cosmological constant Λ leads to the following metric for a black hole:

$$\mathrm{d}\tau^2 = \frac{\mathrm{d}s^2}{c^2} = \left(1 - \frac{2GM}{rc^2} - \frac{\Lambda}{3}r^2\right)\mathrm{d}t^2 - \frac{\mathrm{d}r^2}{c^2 - \frac{2GM}{r} - \frac{\Lambda c^2}{3}r^2} - \frac{r^2}{c^2}\mathrm{d}\varphi^2 \,. \tag{414}$$

Note that this metric does not turn into the Minkowski metric for large values of r. However, in the case that Λ is small, the metric is almost flat for values of r that satisfy $1/\sqrt{\Lambda} \gg r \gg 2Gm/c^2$.

As a result, the inverse square law is also modified:

$$F = -\frac{Gm}{r^2} + \frac{c^2\Lambda}{6}r \,. \tag{415}$$

With the known values of the cosmological constant, the second term is negligible inside the solar system.

* *

In quantum theory, the *gyromagnetic ratio* is an important quantity for any rotating charged system. What is the gyromagnetic ratio for rotating black holes? Challenge 977 ny

* *

A large black hole is, as the name implies, black. Still, it can be seen. If we were to travel towards it in a spaceship, we would note that the black hole is surrounded by a bright circle, like a thin halo. The ring at the radial distance of the photon sphere is due to those photons which come from other luminous objects, then circle the hole, and finally, after one or several turns, end up in our eye. Can you confirm this result? Challenge 978 s

Challenge 979 ny Do moving black holes Lorentz-contract? Black holes do shine a little bit. It is true that the images they form are complex, as light can turn around them a few times before reaching the observer. In addition, the observer has to be far away, so that the effects of curvature are small. All these effects can be taken into account; nevertheless, the question remains subtle. The reason is that the concept of Lorentz contraction makes no sense in general relativity, as the comparison with the uncontracted situation is difficult to define precisely.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

* *

Challenge 980 ny Can you confirm that black holes imply a limit to power? Power is energy change over time. General relativity limits power to $P \leqslant c^5/4G$. In other words, no engine in nature can provide more than $0.92 \cdot 10^{52}$ W or $1.2 \cdot 10^{49}$ horsepower.

Formation of and search for black holes

How might black holes form? At present, at least three possible mechanisms have been distinguished; the question is still a hot subject of research. First of all, black holes could
Ref. 527 have formed during the early stages of the universe. These *primordial black holes* might grow through *accretion*, i.e., through the swallowing of nearby matter and radiation, or
Page 1210 disappear through one of the mechanisms to be studied later on.

Of the *observed* black holes, the so-called *supermassive* black holes are found at the centre of every galaxy studied so far. They have masses in the range from 10^6 to 10^9 solar masses and contain about 0.5 % of the mass of a galaxy. They are conjectured to exist at the centre of all galaxies, and seem to be related to the formation of galaxies themselves. Supermassive black holes are supposed to have formed through the collapse of large dust clouds, and to have grown through subsequent accretion of matter. The latest ideas imply that these black holes accrete a lot of matter in their early stage; the matter falling in emits lots of radiation, which would explain the brightness of quasars. Later on, the rate of accretion slows, and the less spectacular Seyfert galaxies form. It may even be that the supermassive black hole at the centre of the galaxy triggers the formation of stars. Still later, these supermassive black holes become almost dormant, like the one at the centre of the Milky Way.

Ref. 528 On the other hand, black holes can form when old massive stars *collapse*. It is estimated that when stars with at least three solar masses burn out their fuel, part of the matter remaining will collapse into a black hole. Such *stellar* black holes have a mass between one and a hundred solar masses; they can also continue growing through subsequent accretion. This situation provided the first ever candidate for a black hole, Cygnus X-1, which was discovered in 1971.

Recent measurements suggest also the existence of *intermediate* black holes, with masses around a thousand solar masses or more; the mechanisms and conditions for their formation are still unknown.

The search for black holes is a popular sport among astrophysicists. Conceptually, the simplest way to search for them is to look for strong gravitational fields. But only double stars allow one to measure gravitational fields directly, and the strongest ever measured
Ref. 529 is 30 % of the theoretical maximum value. Another way is to look for strong gravitational lenses, and try to get a mass-to-size ratio pointing to a black hole. Still another way is to look at the dynamics of stars near the centre of galaxies. Measuring their motion, one can deduce the mass of the body they orbit. The most favoured method to search for black holes is to look for extremely intense X-ray emission from point sources, using space-based satellites or balloon-based detectors. If the distance to the object is known, its absolute brightness can be deduced; if it is above a certain limit, it must be a black hole, since normal matter cannot produce an unlimited amount of light. This method is being perfected with the aim of directly observing of energy disappearing into a horizon.
Ref. 530 This may in fact have been observed.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

To sum up the experimental situation, measurements show that in all galaxies studied so far – more than a dozen – a supermassive black hole seems to be located at their centre. The masses vary: the black hole at the centre of our own galaxy has about 2.6 million solar masses, while the central black hole of the galaxy M87 has 3000 million solar masses. Ref. 514

About a dozen stellar black holes of between 4 and 20 solar masses are known in the rest of our own galaxy; all have been discovered since 1971, when Cygnus X-1 was found. In the year 2000, intermediate-mass black holes were found. Astronomers are also studying how large numbers of black holes in star clusters behave, how often they collide, and what sort of measurable gravitational waves these collisions produce. The list of discoveries is expected to expand dramatically in the coming years. Ref. 514

Singularities

Solving the equations of general relativity for various initial conditions, one finds that a cloud of dust usually collapses to a *singularity*, i.e., to a point of infinite density. The same conclusion appears when one follows the evolution of the universe backwards in time. In fact, Roger Penrose and Stephen Hawking have proved several mathematical theorems on the necessity of singularities for many classical matter distributions. These theorems assume only the continuity of space-time and a few rather weak conditions on the matter in it. The theorems state that in expanding systems such as the universe itself, or in collapsing systems such as black holes in formation, events with infinite matter density should exist somewhere in the past, or in the future, respectively. This result is usually summarized by saying that there is a mathematical proof that the universe started in a singularity. Ref. 531

In fact, the derivation of the initial singularities makes a hidden, but strong assumption about matter: that dust particles have no proper size. In other words, it is assumed that dust particles are singularities. Only with this assumption can one deduce the existence of initial singularities. However, we have seen that the maximum force principle can be reformulated as a minimum size principle for matter. The argument that there must have been an initial singularity of the universe is thus flawed. The experimental situation is clear: there is overwhelming evidence for an early state of the universe that was extremely hot and dense; but there is *no* evidence for infinite temperature or density.

Mathematically inclined researchers distinguish two types of singularities: those with and without a horizon. The latter ones, the so-called *naked* singularities, are especially strange: for example, a toothbrush can fall into a naked singularity and disappear without leaving any trace. Since the field equations are time invariant, we could thus expect that every now and then, naked singularities emit toothbrushes. (Can you explain why 'dressed' singularities are less dangerous?) Challenge 981 ny

To avoid the spontaneous appearance of toothbrushes, over the years many people have tried to discover some theoretical principles forbidding the existence of naked singularities. It turns out that there are two such principles. The first is the maximum force or maximum power principle we encountered above. The maximum force implies that no infinite force values appear in nature; in other words, there are no naked singularities in nature. This statement is often called *cosmic censorship*. Obviously, if general relativity were not the correct description of nature, naked singularities *could* still appear. Cosmic censorship is thus still discussed in research articles. The experimental search for naked Ref. 532

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

singularities has not yielded any success; in fact, there is not even a candidate observation for the less abstruse dressed singularities. But the theoretical case for 'dressed' singularities is also weak. Since there is no way to interact with anything behind a horizon, it is futile to discuss what happens there. There is no way to prove that behind a horizon a singularity exists. Dressed singularities are articles of faith, not of physics.

In fact, there is another principle preventing singularities, namely *quantum theory*. Whenever we encounter a prediction of an infinite value, we have extended our description of nature to a domain for which it was not conceived. To speak about singularities, one must assume the applicability of pure general relativity to very small distances and very high energies. As will become clear in the next two parts of this book, nature does not allow this: the combination of general relativity and quantum theory shows that it makes no sense to talk about 'singularities', nor about what happens 'inside' a black hole horizon. The reason is that time and space are not continuous at very small scales. *

Page 1436
Page 1401

A QUIZ – IS THE UNIVERSE A BLACK HOLE?

Could it be that we live inside a black hole? Both the universe and black holes have horizons. Interestingly, the horizon distance r_0 of the universe is about

$$r_0 \approx 3ct_0 \approx 4 \cdot 10^{26}\,\mathrm{m} \tag{416}$$

and its matter content is about

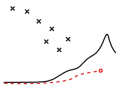
$$m_0 \approx \frac{4\pi}{3}\rho_0 r_0^3 \quad \text{whence} \quad \frac{2Gm_0}{c^2} = 72\pi G\rho_0 c t_0^3 = 6 \cdot 10^{26}\,\mathrm{m} \tag{417}$$

for a density of $3 \cdot 10^{-27}\,\mathrm{kg/m^3}$. Thus we have

$$r_0 \approx \frac{2Gm_0}{c^2}\,, \tag{418}$$

which is similar to the black hole relation $r_S = 2Gm/c^2$. Is this a coincidence? No, it is not: all systems with high curvature more or less obey this relation. But are we nevertheless falling into a large black hole? You can answer that question by yourself.

Challenge 982 ny
Challenge 983 ny



* Many physicists are still wary of making such strong statements at this point; and there are still some who claim that space and time are continuous even down to the smallest distances. Our discussion of quantum theory, and the first sections of the final part of our mountain ascent, will give the precise arguments leading to the opposite conclusion.

Page 1396

Chapter 21

DOES SPACE DIFFER FROM TIME?

> Tempori parce.*
>
> Seneca

People in a bad mood say that time is our master. Nobody says that of space. Time and space are obviously different in everyday life. But what is the precise difference between them in general relativity? And do we need them at all? In general relativity it is assumed that we live in a (pseudo-Riemannian) space-time of variable curvature. The curvature is an observable and is related to the distribution and motion of matter and energy in the way described by the field equations.

However, there is a fundamental problem. The equations of general relativity are invariant under numerous transformations which *mix* the coordinates x_0, x_1, x_2 and x_3. For example, the viewpoint transformation

$$\begin{aligned} x'_0 &= x_0 + x_1 \\ x'_1 &= -x_0 + x_1 \\ x'_2 &= x_2 \\ x'_3 &= x_3 \end{aligned} \tag{419}$$

is allowed in general relativity, and leaves the field equations invariant. You might want to search for other examples.

Challenge 984 ny

This has a consequence that is clearly in sharp contrast with everyday life: diffeomorphism invariance makes it *impossible* to distinguish space from time *inside* general relativity. More explicitly, the coordinate x_0 cannot simply be identified with the physical time t, as implicitly done up to now. This identification is only possible in *special* relativity. In special relativity the invariance under Lorentz (or Poincaré) transformations of space and time singles out energy, linear momentum and angular momentum as the fundamental observables. In general relativity, there is *no* (non-trivial) metric isometry group; consequently, there are *no* basic physical observables singled out by their characteristic of being conserved. But invariant quantities are necessary for communication! In fact, we can *talk* to each other only because we live in an approximately *flat* space-time: if the angles of a triangle did not add up to π (two right angles), there would be *no* invariant quantities and we would not be able to communicate.

* 'Care about time.' Lucius Annaeus Seneca (*c.* 4 BCE–65), *Epistolae* 88, 39.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

How have we managed to sweep this problem under the rug so far? We have done so in several ways. The simplest was to always require that in some part of the situation under consideration space-time was our usual flat Minkowski space-time, where x_0 can be identified with t. We can fulfil this requirement either at infinity, as we did around spherical masses, or in zeroth approximation, as we did for gravitational radiation and for all other perturbation calculations. In this way, we eliminate the free mixing of coordinates and the otherwise missing invariant quantities appear as expected. This pragmatic approach is the usual way out of the problem. In fact, it is used in some otherwise excellent texts on general relativity that preclude any deeper questioning of the issue.

Ref. 488

A common variation of this trick is to let the distinction 'sneak' into the calculations by the introduction of matter and its properties, or by the introduction of radiation. The material properties of matter, for example their thermodynamic state equations, always distinguish between space and time. Radiation does the same, by its propagation. Obviously this is true also for those special combinations of matter and radiation called clocks and metre bars. In fact, the method of introducing matter is the same as the method of introducing Minkowski space-time, if one looks closely: properties of matter are always defined using space-time descriptions of special relativity.*

Another variation of the pragmatic approach is the use of the cosmological time coordinate. An isotropic and homogeneous universe does have a preferred time coordinate, namely the one used in all the tables on the past and the future of the universe. This method is in fact a combination of the previous two.

Page 577, page 800

But we are on a special quest here. We want to *understand* motion in principle, not only to calculate it in practice. We want a *fundamental* answer, not a pragmatic one. And for this we need to know how the positions x_i and time t are connected, and how we can define invariant quantities. The question also prepares us for the task of combining gravity with quantum theory, which is the aim of the final part of our mountain ascent.

A fundamental solution requires a description of clocks together with the system under consideration, and a deduction of how the reading t of a clock relates to the behaviour of the system in space-time. But we know that any description of a system requires measurements: for example, in order to determine the initial conditions. And initial conditions require space and time. We thus enter a vicious circle: that is precisely what we wanted to avoid in the first place.

A suspicion arises. Is there in fact a fundamental difference between space and time? Let us take a tour of various ways to investigate this question.

Can space and time be measured?

In order to distinguish between space and time in general relativity, we must be able to measure them. But already in the section on universal gravity we have mentioned the impossibility of measuring lengths, times and masses with gravitational effects alone. Does this situation change in general relativity? Lengths and times are connected by the speed of light, and in addition lengths and masses are connected by the gravitational

Page 317

* We note something astonishing here: the inclusion of some condition at small distances (matter) has the same effect as the inclusion of some condition at infinity. Is this just coincidence? We will come back to this issue in the last part of our mountain ascent.

Challenge 985 ny
Page 1445

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

constant. Despite this additional connection, it takes only a moment to convince oneself that the problem persists.

In fact, we need *electrodynamics* to solve it. It is only be using the elementary charge Ref. 533 e that we can form length scales, of which the simplest one is

$$l_{\text{emscale}} = \frac{e}{\sqrt{4\pi\varepsilon_0}} \frac{\sqrt{G}}{c^2} \approx 1.4 \cdot 10^{-36}\,\text{m} \,. \tag{420}$$

Page 678 Here, ε_0 is the permittivity of free space. Alternatively, we can argue that *quantum mechanics* provides a length scale, since one can use the quantum of action $\hbar$ to define the length scale

$$l_{\text{qtscale}} = \sqrt{\frac{\hbar G}{c^3}} \approx 1.6 \cdot 10^{-35}\,\text{m} \,, \tag{421}$$

which is called the *Planck length* or *Planck's natural length unit*. However, this does not change the argument, because one needs electrodynamics to measure the value of $\hbar$. The equivalence of the two arguments is shown by rewriting the elementary charge e as a combination of nature's fundamental constants:

$$e = \sqrt{4\pi\varepsilon_0 c\hbar\alpha} \,. \tag{422}$$

Here, $\alpha \approx 1/137.06$ is the fine-structure constant that characterizes the strength of electromagnetism. In terms of α, expression (420) becomes

$$l_{\text{scale}} = \sqrt{\frac{\alpha\hbar G}{c^3}} = \sqrt{\alpha}\, l_{\text{Pl}} \,. \tag{423}$$

Summing up, every length measurement is based on the electromagnetic coupling constant α and on the Planck length. Of course, the same is true for time and mass measurements. There is thus no way to define or measure lengths, times and masses using gravitation or general relativity only.* Challenge 986 e

Given this sobering result, we can ask whether in general relativity space and time are really required at all.

Are space and time necessary?

Ref. 535 Robert Geroch answers this question in a beautiful five-page article. He explains how to formulate the general theory of relativity without the use of space and time, by taking as starting point the physical observables only.

He starts with the set of all observables. Among them there is one, called v, which stands out. It is the only observable which allows one to say that for any two observables

Ref. 534 * In the past, John Wheeler used to state that his *geometrodynamic clock*, a device which measures time by bouncing light back and forth between two parallel mirrors, was a counter-example; that is not correct, however. Can you confirm this? Challenge 987 s

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

a_1, a_2 there is a third one a_3, for which

$$(a_3 - v) = (a_1 - v) + (a_2 - v) \,. \tag{424}$$

Such an observable is called the *vacuum*. Geroch shows how to use such an observable to construct the derivatives of observables. Then the so-called Einstein algebra can be built, which comprises the whole of general relativity.

Usually one describes motion by deducing space-time from matter observables, by calculating the evolution of space-time, and then by deducing the motion of matter following from it. Geroch's description shows that the middle step, and thus the use of space and time, is not necessary.

Indirectly, the principle of maximum force makes the same statement. General relativity can be derived from the existence of limit values for force or power. Space and time are only tools needed to translate this principle into consequences for real-life observers.

Thus, it is possible to formulate general relativity without the use of space and time. Since both are unnecessary, it seems unlikely that there should be a fundamental difference between them. Nevertheless, one difference is well-known.

Do closed timelike curves exist?

Is it possible that the time coordinate behaves, at least in some regions, like a torus? When we walk, we can return to the point of departure. Is it possible, to come back in time to where we have started? The question has been studied in great detail. The standard reference is the text by Hawking and Ellis; they list the required properties of space-time, explaining which are mutually compatible or exclusive. They find, for example, that space-times which are smooth, globally hyperbolic, oriented and time-oriented do not contain any such curves. It is usually assumed that the observed universe has these properties, so that observation of closed timelike curves is unlikely. Indeed, no candidate has ever been suggested. Later on, we will show that searches for such curves at the microscopic scale have also failed to find any.

Ref. 494

Page 1219

The impossibility of closed timelike curves seems to point to a difference between space and time. But in fact, this difference is only apparent. All these investigations are based on the behaviour of matter. Thus these arguments assume a specific distinction between space and time right from the start. In short, this line of enquiry cannot help us to decide whether space and time differ. Let us look at the issue in another way.

Is general relativity local? – The hole argument

When Albert Einstein developed general relativity, he had quite some trouble with diffeomorphism invariance. Most startling is his famous *hole argument*, better called the *hole paradox*. Take the situation shown in Figure 315, in which a mass deforms the space-time around it. Einstein imagined a small region of the vacuum, the *hole*, which is shown as a small ellipse. What happens if we somehow change the curvature inside the hole while leaving the situation outside it unchanged, as shown in the inset of the picture?

Ref. 536

On the one hand, the new situation is obviously physically different from the original one, as the curvature inside the hole is different. This difference thus implies that the curvature outside a region does not determine the curvature inside it. That is extremely

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

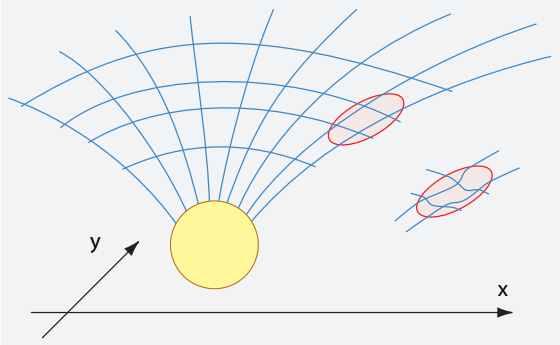

FIGURE 315 A 'hole' in space

unsatisfactory. Worse, if we generalize this operation to the time domain, we seem to get the biggest nightmare possible in physics: determinism is lost.

On the other hand, general relativity is diffeomorphism invariant. The deformation shown in the figure is a diffeomorphism; so the new situation must be physically equivalent to the original situation.

Which argument is correct? Einstein first favoured the first point of view, and therefore dropped the whole idea of diffeomorphism invariance for about a year. Only later did he understand that the second assessment is correct, and that the first statement makes a fundamental mistake: it assumes an independent existence of the coordinate axes x and y, as shown in the figure. But during that deformation, the coordinates x and y automatically change as well, so that there is *no* physical difference between the two situations.

The moral of the story is that *there is no difference between space-time and gravitational field*. Space-time is a quality of the field, as Einstein put it, and not an entity with a separate existence, as suggested by the graph. Coordinates have no physical meaning; only distances (intervals) in space and time have one. In particular, diffeomorphism invariance proves that *there is no flow of time*. Time, like space, is only a relational entity: time and space are relative; they are not absolute.

The relativity of space and time has practical consequences. For example, it turns out that many problems in general relativity are equivalent to the Schwarzschild situation, even though they appear completely different at first sight. As a result, researchers have 'discovered' the Schwarzschild solution (of course with different coordinate systems) over twenty times, often thinking that they had found a new, unknown solution. We will now discuss a startling consequence of this insight.

Is the Earth hollow?

The *hollow Earth hypothesis*, i.e., the conjecture that we live on the *inside* of a sphere, was popular in paranormal circles around the year 1900, and still remains so among certain eccentrics today, especially in Britain, Germany and the US. They maintain, as illustrated in Figure 316, that the solid Earth *encloses* the sky, together with the Moon, the Sun and the stars. Most of us are fooled by education into another description, because we are brought up to believe that light travels in straight lines. Get rid of this wrong belief, they say, and the hollow Earth appears in all its glory.

Page 61

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

FIGURE 316 A model of the hollow Earth theory (© Helmut Diehl)

Interestingly, the reasoning is correct. There is *no way* to disprove this sort of description of the universe. In fact, as the great Austrian physicist Roman Sexl used to explain, the diffeomorphism invariance of general relativity even proclaims the equivalence between the two views. The fun starts when either of the two camps wants to tell the other that *only* its own description can be correct. You might check that any such argument is wrong; it is fun to slip into the shoes of such an eccentric and to defend the hollow Earth hypothesis against your friends. It is easy to explain the appearance of day and night, of the horizon, and of the satellite images of the Earth. It is easy to explain what happened during the flight to the Moon. You can drive many bad physicists crazy in this way. The usual description and the hollow Earth description are exactly equivalent. Can you confirm that even quantum theory, with its introduction of length scales into nature, does not change this situation?

Ref. 537

Challenge 988 e

Challenge 989 s

Such investigations show that diffeomorphism invariance is not an easy symmetry to swallow. But it is best to get used to it now, as the rest of our adventure will throw up even more surprises. Indeed, in the final part of our walk we will discover that there is an even larger symmetry of nature that is similar to the change in viewpoint from the hollow Earth view to the standard view. This symmetry, space-time duality, is valid not only for distances measured from the centre of the Earth, but for distances measured from any point in nature.

Page 1445

Are space, time and mass independent?

We can conclude from this short discussion that there is no fundamental distinction between space and time in general relativity. Pragmatic distinctions, using matter, radiation or space-time at infinity, are the only possible ones.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In the last part of our adventure we will discover that even the inclusion of quantum theory is consistent with this view. We will show explicitly that no distinction is possible in principle. We will discover that mass and space-time are on an equal footing, and that, in a sense, particles and vacuum are made of the same substance. Distinctions between space and time turn out to be possible only at low, everyday energies.

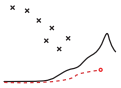
Page 1413

In the beginning of our mountain ascent we found that we needed matter to define space and time. Now we have found that we even need matter to *distinguish* between space and time. Similarly, in the beginning we found that space and time are required to define matter; now we have found that we even need *flat* space-time to define it.

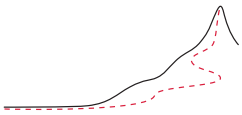
Page 317

Page 558

In summary, general relativity does not provide a way out of the circular reasoning we discovered in Galilean physics. Indeed, it makes the issue even less clear than before. Continuing the mountain ascent is really worth the effort.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 22

GENERAL RELATIVITY IN TEN POINTS – A SUMMARY FOR THE LAYMAN

Sapientia felicitas.*

General relativity is the final description of *paths of motion*, or if one prefers, of *macroscopic motion*. General relativity describes how the observations of motion of *any* two observers are related to each other; it also describes motion due to gravity. In fact, general relativity is based on the following observations:

— All observers agree that there is a 'perfect' speed in nature, namely a common maximum energy speed relative to matter. This speed is realized by massless radiation, such as light or radio signals.
— All observers agree that there is a 'perfect' force in nature, a common maximum force that can be realized or measured by realistic observers. This force is realized on event horizons.

These two statements contain the full theory of relativity. From them we deduce:

— Space-time consists of events in 3 + 1 *continuous dimensions*, with a variable curvature. The curvature can be deduced from distance measurements among events or from tidal effects. We thus live in a pseudo-Riemannian space-time. Measured times, lengths and curvatures vary from observer to observer.
— Space-time and space are *curved near mass and energy*. The curvature at a point is determined by the energy–momentum density at that point, and described by the field equations. When matter and energy move, the space curvature moves along with them. A built-in delay in this movement renders faster-than-light transport of energy impossible. The proportionality constant between energy and curvature is so small that the curvature is not observed in everyday life; only its indirect manifestation, namely gravity, is observed.
— Space is also *elastic*: it prefers being flat. Being elastic, it can oscillate independently of matter; one then speaks of gravitational radiation or of gravity waves.
— Freely falling matter moves along *geodesics*, i.e., along paths of maximal length in curved space-time; in space this means that light bends when it passes near large masses by twice the amount predicted by universal gravity.
— To describe gravitation one *needs* curved space-time, i.e., general relativity, *at the latest* whenever distances are of the order of the Schwarzschild radius $r_S = 2Gm/c^2$. When

* 'Wisdom is happiness.' A well-known inscription in Oxford University.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

distances are much larger than this value, the relativistic description with gravity and gravitomagnetism (frame-dragging) is sufficient. When distances are even larger, the description by universal gravity, namely $a = Gm/r^2$, together with flat Minkowski space-time, will do as a first approximation.
— Space and time are not distinguished globally, but only locally. *Matter* is required to make the distinction.

In addition, all the matter and energy we observe in the sky lead us to the following conclusions:

— On the cosmological scale, everything moves away from everything else: the universe is *expanding*. This expansion of space-time is described by the field equations.
— The universe has a *finite age*; this is the reason for the darkness of the sky at night. A horizon limits the measurable space-time intervals to about fourteen thousand million years.

The accuracy of the description

Was general relativity worth the effort? The discussion of its accuracy is most conveniently split into two sets of experiments. The first set consists of measurements of how *matter moves*. Do objects really follow geodesics? As summarized in Table 56, all experiments agree with the theory to within measurement errors, i.e., at least within 1 part in 10^{12}. In short, the way matter falls is indeed well described by general relativity.

Ref. 538

Ref. 539

The second set of measurements concerns the dynamics of space-time itself. Does *space-time move* following the field equations of general relativity? In other words, is space-time really bent by matter in the way the theory predicts? Many experiments have been performed, near to and far from Earth, in both weak and strong fields. All agree with the predictions to within measurement errors. However, the best measurements so far have only about 3 significant digits. Note that even though numerous experiments have been performed, there are only few *types* of tests, as Table 56 shows. The discovery of a new type of experiment almost guarantees fame and riches. Most sought after, of course, is the direct detection of gravitational waves.

Ref. 538, Ref. 539

Challenge 990 ny

Another comment on Table 56 is in order. After many decades in which all measured effects were only of the order v^2/c^2, several so-called *strong field effects* in pulsars allowed us to reach the order v^4/c^4. Soon a few effects of this order should also be detected even inside the solar system, using high-precision satellite experiments. The present crown of all measurements, the gravity wave emission delay, is the only v^5/c^5 effect measured so far.

Ref. 538

Page 531

The difficulty of achieving high precision for space-time curvature measurements is the reason why mass is measured with balances, always (indirectly) using the prototype kilogram in Paris, instead of defining some standard curvature and fixing the value of G. Indeed, no useful terrestrial curvature experiment has ever been carried out. A breakthrough in this domain would make the news. The terrestrial curvature methods currently available would not even allow one to define a kilogram of gold or of oranges with a precision of a single kilogram!

Another way to check general relativity is to search for alternative descriptions of gravitation. Quite a number of alternative theories of gravity have been formulated and

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 539, Ref. 542 studied, but so far, only general relativity is in agreement with all experiments.

In summary, as Thibault Damour likes to explain, general relativity is at least 99.999 999 999 9 % correct concerning the motion of matter and energy, and at least Ref. 538 99.9 % correct about the way matter and energy curve and move space-time. No exceptions, no anti-gravity and no unclear experimental data are known. All motion on Earth and in the skies is described by general relativity. Albert Einstein's achievement has no flaws.

We note that general relativity has not been tested for microscopic motion. In this context, *microscopic motion* is any motion for which the action is around the quantum of action, namely 10^{-34} Js. This issue is central to the last part of our adventure.

Research in general relativity and cosmology

Ref. 543 Research in general relativity is more intense than ever.*

* *

The most interesting experimental studies at present are those of double pulsars, the search for gravitational waves and various dedicated satellites; among others a special satellite will capture all possible pulsars of the galaxy. All these experiments will allow experimental tests in domains that have not been accessible up to now.

* There is even a free and excellent internet-based research journal, called *Living Reviews in Relativity*, to be found at the www.livingreviews.org website.

* *

The description of collisions and many-body problems, involving stars, neutron stars and black holes helps astrophysicists to improve their understanding of the rich behaviour they observe in their telescopes. Ref. 544

* *

The study of the early universe and of elementary particle properties, with phenomena such as *inflation*, a short period of accelerated expansion during the first few seconds, is still an important topic of investigation. Ref. 545

* *

The study of chaos in the field equations is of fundamental interest in the study of the early universe, and may be related to the problem of galaxy formation, one of the biggest open problems in physics. Ref. 546

* *

Gathering data about galaxy formation is the main aim of many satellite systems and purpose-build telescopes. The main focus is the search for localized cosmic microwave background anisotropies due to protogalaxies. Ref. 547

* *

The determination of the cosmological parameters, such as the matter density, the curvature and the vacuum density, is a central effort of modern astrophysics. Ref. 490

* *

Astrophysicists regularly discover new phenomena in the skies. For example, the various types of gamma-ray bursts, X-ray bursts and optical bursts are still not completely understood. Gamma-ray bursts, for example, can be as bright as 10^{17} sun-like stars combined; however, they last only a few seconds. More details on this research are given later on. Ref. 548 Page 1211

* *

A computer database of all solutions of the field equations is being built. Among other things, researchers are checking whether they really are all different from each other. Ref. 549

* *

Solutions with non-trivial topology, such as wormholes and particle-like solutions, constitue a fascinating field of enquiry, related to quantum gravity. Ref. 551 Page 1219

* *

Other formulations of general relativity, describing space-time with quantities other than the metric, are continuously being developed, in the hope of clarifying its relationship to the quantum world. The so-called Ashtekar variables are such a modern description. Ref. 552

* *

The unification of quantum physics and general relativity, the topic of the final part of

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

this mountain ascent, will occupy researchers for many years to come. Ref. 553

* *

Finally, the teaching of general relativity, which for many decades has been hidden behind Greek indices, differential forms and other antididactic methods, will benefit greatly from future improvements focusing more on the physics and less on the formalism. Ref. 554

In short, general relativity is still an extremely interesting field of research and important discoveries are still expected.

Could general relativity be different?

The constant of gravitation provides a limit for the density and the acceleration of objects, as well as for the power of engines. We based all our deductions on its invariance. Is it possible that the constant of gravitation G changes from place to place or that it changes with time? The question is tricky. At first sight, the answer is a loud: 'Yes, of course! Just see what happens when the value of G is changed in formulae.' However, this answer is wrong, as it was wrong for the speed of light c. Page 469

Since the constant of gravitation enters into our definition of gravity and acceleration, and thus, even if we do not notice it, into the construction of all rulers, all measurement standards and all measuring set-ups, there is *no way* to detect whether its value actually varies. No imaginable experiment could detect a variation. Every measurement of force is, whether we like it or not, a comparison with the limit force. There is no way, in principle, to check the invariance of a standard. This is even more astonishing because measurements of this type are regularly reported, as in Table 56. But the result of any such experiment is easy to predict: no change will ever be found. Challenge 991 ny Page 628

Could the number of space dimension be different from 3? This issue is quite involved. For example, three is the smallest number of dimensions for which a vanishing Ricci tensor is compatible with non-vanishing curvature. On the other hand, more than three dimensions give deviations from the inverse square 'law' of gravitation. So far, there are no data pointing in this direction.

Could the equations of general relativity be different? Theoreticians have explored many alternative theories, such as scalar-tensor theories, theories with torsion, or theories which break Lorentz invariance. However, almost none of the alternative theories proposed so far seem to fit experimental data. However, two candidates might exist.

The inclusion of torsion in the field equations, a possible extension of the theory, is one of the more promising attempts to include particle spin in general relativity. The inclusion of torsion in general relativity does not require new fundamental constants; indeed, the absence of torsion was assumed in the Raychaudhuri equation. The use of the extended Raychaudhuri equation, which includes torsion, should allow one to deduce the full Einstein–Cartan theory from the maximum force principle. This issue is a topic of research. Ref. 550 Ref. 555

Finally, there is one experimental result that still is unexplained. The rotation speed of matter far from the centre of galaxies does not seem to be consistent with the inverse square dependence. There could be many reasons for this effect. The most popular models are the existence of dark matter on one side or a modification in the field equations

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Ref. 556 for astronomically large distances on the other side. The dark matter model assumes that we have difficulties observing something, the modified dynamics model assumes that we missed something in the equations. The issue is still open.

The limits of general relativity

Despite its successes, the description of motion presented so far is unsatisfactory; maybe Challenge 992 e you already have some gut feeling about certain unresolved issues.

First of all, even though the speed of light is the starting point of the whole theory, we still do not know what light actually *is*. This will be our next topic.

Secondly, we have seen that everything falls along geodesics. But a mountain does not fall. Somehow the matter below prevents it from falling. How? And where does mass come from anyway? What is mass? What is matter? General relativity does not provide an answer; in fact, it does not describe matter *at all*. Einstein used to say that the left-hand side of the field equations, describing the curvature of space-time, was granite, while the right-hand side, describing matter, was sand. Indeed, at this point we still do not know what matter and mass are. As already remarked, to change the sand into rock we first need quantum theory and then, in a further step, its unification with relativity. This is the programme for the rest of our adventure.

We have also seen that matter is necessary to clearly distinguish between space and time, and in particular, to understand the working of clocks, metre bars and balances. In particular, one question remains: why are there units of mass, length and time in nature *at all*? This deep question will also be addressed in the following part of our ascent.

Finally, we know little about the vacuum. We need to understand the magnitude of the cosmological constant and the number of space-time dimensions. Only then can we answer the simple question: Why is the sky so far away? General relativity does not help here. Worse, the smallness of the cosmological constant contradicts the simplest version of quantum theory; this is one of the reasons why we still have quite some height to scale Page 1396 before we reach the top of Motion Mountain.

In short, to describe motion well, we need a more precise description of light, of matter and of the vacuum. In other words, we need to know more about everything we know. Page 1152 Otherwise we cannot hope to answer questions about mountains, clocks and stars. In a sense, it seems that we have not achieved much. Fortunately, this is not true. We have learned so much that for the following topic we are forced to go backwards, to situations *without* gravity, i.e., back to the framework of special relativity. That is the next, middle section of our mountain ascent. Despite this simplification to flat space-time, a lot of fun awaits us there.

> It's a good thing we have gravity, or else when birds died they'd just stay right up there. Hunters would be all confused.
>

starting point. This page mentions most of the English-language relativity resources available on the web. Links in other languages can be found with search engines. Cited on page 405.

303 Observations of gamma ray bursts show that the speed of light does not depend on the lamp speed to within one part in 10^{20}, as shown by K. Brecher, *Bulletin of the American Physical Society* **45**, 2000. He assumed that both sides of the burster emit light. The large speed difference and the pulse sharpness then yield this result. See also his older paper K. Brecher, Is the speed of light independent of the source?, *Physics Letters* **39**, pp. 1051–1054, Errata 1236, 1977. Measuring the light speed from rapidly moving stars is another way. Some of these experiments are not completely watertight, however. There is a competing theory of electrodynamics, due to Ritz, which maintains that the speed of light is c only when measured with respect to the source; The light from stars, however, passes through the atmosphere, and its speed might thus be reduced to c.

The famous experiment with light emitted from rapid pions at CERN is not subject to this criticism. It is described in T. Alväger, J. M. Bailey, F. J. M. Farley, J. Kjellman & I. Wallin, Test of the second postulate of relativity in the GeV region, *Physics Letters* **12**, pp. 260–262, 1964. See also T. Alväger & al., Velocity of high-energy gamma rays, *Arkiv för Fysik* **31**, pp. 145–157, 1965.

Another precise experiment at extreme speeds is described by G. R. Kalbfleisch, N. Baggett, E. C. Fowler & J. Alspector, Experimental comparison of neutrino, anti-neutrino, and muon velocities, *Physical Review Letters* **43**, pp. 1361–1364, 1979. Cited on page 406.

374 Similar statements are made by Michael Duff in several of his publications. See, for example, M. J. Duff, Comment on time-variation of fundamental constants, arxiv.org/abs/hep-th/0208093. Cited on page 469.

375 The quote is form a letter of Gibbs to the American Academy of Arts and Sciences, in which he thanks the Academy for their prize. The letter was read in a session of the Academy and thus became part of the proceedings: J. W. Gibbs, Proceedings of the American Academy of Arts and Sciences, **16**, p. 420, 1881. Cited on page 472.

376 It seems that the first published statement of the principle was in the year 2000 edition of this text, in the chapter on gravitation and relativity. The present author discovered the maximum force principle in 1998, when searching for a way to derive the results of chapter 52 that would be so simple that it would convince even a secondary-school student. The reference is Christoph Schiller, *Motion Mountain – The Adventure of Physics*, found at www.motionmountain.eu. The idea of a maximum force was also proposed by Gary Gibbons in 2002 (see reference below). Nowadays Gary Gibbons is more cautious than the author about whether the maximum force can be seen as an actual physical principle (despite the title of his paper). The approach of a maximum force was discussed in various usenet discussion groups in the early twenty-first century. These discussion showed that the idea of a maximum force (and a maximum power) were known to some people, but that before Gibbons and the author few had put it in writing. Also this physics discovery was thus made much too late. In short, only the idea to raise maximum force or power to a *principle* seems to be original; it was published first in the reference following this one and then in C. Schiller, General relativity and cosmology derived from principle of maximum power or force, *International Journal of Theoretical Physics* **44**, pp. 1629–1647, 2005, preprint at arxiv.org/abs/physics/0607090. Cited on page 472.

377 C. Schiller, Maximum force and minimum distance: physics in limit statements, part of this text and downloadable at www.motionmountain.eu/MotionMountain-Part6.pdf, preprint at arxiv.org/abs/physics/0309118. Cited on pages 474, 477, 486, and 495.

392 The simplest historical source is Albert Einstein, *Sitzungsberichte der Preussischen Akademie der Wissenschaften* II pp. 844–846, 1915. It is the first explanation of the general theory of relativity, in only three pages. The theory is then explained in detail in the famous article Albert Einstein, Die Grundlage der allgemeinen Relativitätstheorie, *Annalen der Physik* **49**, pp. 769–822, 1916. The historic references can be found in German and English in John Stachel, ed., *The Collected Papers of Albert Einstein*, Volumes 1–9, Princeton University Press, 1987–2004.

Below is a selection of English-language textbooks for deeper study, in ascending order of depth and difficulty:

— An entertaining book without any formulae, but nevertheless accurate and detailed, is the paperback by Igor Novikov, *Black Holes and the Universe*, Cambridge University Press, 1990.
— Almost no formulae, but loads of insight, are found in the enthusiastic text by John A. Wheeler, *A Journey into Gravity and Spacetime*, W.H. Freeman, 1990.
— An excellent didactical presentation is Edwin F. Taylor & John A. Wheeler, *Exploring Black Holes: Introduction to General Relativity*, Addison Wesley Longman, 2000.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

— Beauty, simplicity and shortness are the characteristics of Malcolm Ludvigsen, *General Relativity, a Geometric Approach*, Cambridge University Press, 1999.
— Good explanation is the strength of Bernard Schutz, *Gravity From the Ground Up*, Cambridge University Press, 2003.
— A good overview of experiments and theory is given in James Foster & J. D. Nightingale, *A Short Course in General Relativity*, Springer Verlag, 2nd edition, 1998.
— A pretty text is Sam Lilley, *Discovering Relativity for Yourself*, Cambridge University Press, 1981.
— A modern text is by Ray d'Inverno *Introducing Einstein's Relativity*, Clarendon Press, 1992. It includes an extended description of black holes and gravitational radiation, and regularly refers to present research.
— A beautiful, informative and highly recommended text is Hans C. Ohanian & Remo Ruffini, *Gravitation and Spacetime*, W.W. Norton & Co., 1994.
— A well written and modern book, with emphasis on the theory, by one of the great masters of the field is Wolfgang Rindler, *Relativity – Special, General and Cosmological*, Oxford University Press, 2001.
— A classic is Steven Weinberg, *Gravitation and Cosmology*, Wiley, 1972.
— The passion of general relativity can be experienced also in John Klauder, ed., *Magic without Magic: John Archibald Wheeler – A Collection of Essays in Honour of His Sixtieth Birthday*, W.H. Freeman & Co., 1972.
— An extensive text is Kip S. Thorne, *Black Holes and Time Warps – Einstein's Outrageous Legacy*, W.W. Norton, 1994.
— The most mathematical – and toughest – text is Robert M. Wald, *General Relativity*, University of Chicago Press, 1984.
— Much information about general relativity is available on the internet. As a good starting point for US-American material, see the math.ucr.edu/home/baez/physics/ website.

There is still a need for a large and modern textbook on general relativity, with colour material, that combines experimental and theoretical aspects.

For texts in other languages, see the next reference. Cited on pages 498, 535, 536, 555, and 557.

393 A beautiful German teaching text is the classic G. Falk & W. Ruppel, *Mechanik, Relativität, Gravitation – ein Lehrbuch*, Springer Verlag, third edition, 1983.

A practical and elegant booklet is Ulrich E. Schröder, *Gravitation – Einführung in die allgemeine Relativitätstheorie*, Verlag Harri Deutsch, Frankfurt am Main, 2001.

A modern reference is Torsten Fliessbach, *Allgemeine Relativitätstheorie*, Akademischer Spektrum Verlag, 1998.

Excellent is Hubert Goenner, *Einführung in die spezielle und allgemeine Relativitätstheorie*, Akademischer Spektrum Verlag, 1996.

In Italian, there is the beautiful, informative, but expensive Hans C. Ohanian & Remo Ruffini, *Gravitazione e spazio-tempo*, Zanichelli, 1997. It is highly recommended. A modern update of that book would be without equals. Cited on pages 498, 530, 531, 535, 536, 555, 557, and 645.

394 P. Mohazzabi & J. H. Shea, High altitude free fall, *American Journal of Physics* **64**, pp. 1242–1246, 1996. As a note, due to a technical failure Kittinger had his hand in (near) vacuum during his ascent, without incurring any permanent damage. On the consequences of human exposure to vacuum, see the www.sff.net/people/geoffrey.landis/vacuum.html website. Cited on page 498.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

400 R.F.C. Vessot & al., Test of relativistic gravitation with a space-borne hydrogen maser, *Physical Review Letters* **45**, pp. 2081–2084, 1980. The experiment was performed in 1976; there are more than a dozen co-authors involved in this work, which involved shooting a maser into space with a scout missile to a height of *c.* 10 000 km. Cited on page 502.

401 L. Briatore & S. Leschiutta, Evidence for Earth gravitational shift by direct atomic-time-scale comparison, *Il Nuovo Cimento* **37B**, pp. 219–231, 1977. Cited on page 502.

402 More information about tides can be found in E. P. Clancy, *The Tides*, Doubleday, New York, 1969. Cited on page 503.

403 The expeditions had gone to two small islands, namely to Sobral, north of Brazil, and to Principe, in the gulf of Guinea. The results of the expedition appeared in *The Times* before they appeared in a scientific journal. Today this would be seen as a gross violation of scientific honesty. The results were published as F. W. Dyson, A. S. Eddington & C. Davidson, *Philosophical Transactions of the Royal Society (London)* **220A**, p. 291, 1920, and *Memoirs of the Royal Astronomical Society* **62**, p. 291, 1920. Cited on page 504.

404 A good source for images of space-time is the text by G. F. R. Ellis & R. Williams, *Flat and Curved Space-times*, Clarendon Press, Oxford, 1988. Cited on page 505.

405 J. Droste, Het veld van een enkel centrum in Einstein's theorie der zwaartekracht, en de beweging van een stoffelijk punt, *Verslag gew. Vergad. Wiss. Amsterdam* **25**, pp. 163–180, 1916. Cited on page 506.

406 The name *black hole* was introduced in 1967 at a pulsar conference, as described in his autobiography by John A. Wheeler, *Geons, Black Holes, and Quantum Foam: A Life in Physics*, W.W. Norton, 1998, pp. 296–297: 'In my talk, I argued that we should consider the possibility that at the center of a pulsar is a gravitationally completely collapsed object. I remarked that one couldn't keep saying "gravitationally completely collapsed object" over and over. One needed a shorter descriptive phrase. "How about black hole?" asked someone in the audience. I had been searching for just the right term for months, mulling it over in bed, in the bathtub, in my car, whenever I had quiet moments. Suddenly, this name seemed exactly right. When I gave a more formal ... lecture ... a few weeks later on, on December 29, 1967, I used the term, and then included it into the written version of the lecture published in the spring of 1968 ... I decided to be casual about the term "black hole", dropping it into the lecture and the written version as if it were an old familiar friend. Would it catch on? Indeed it did. By now every schoolchild has heard the term.'

The widespread use of the term began with the article by R. Ruffini & J. A. Wheeler, Introducing the black hole, *Physics Today* **24**, pp. 30–41, January 1971.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

In his autobiography, Wheeler also writes that the expression 'black hole has no hair' was criticized as 'obscene' by Feynman. An interesting comment by a physicist who used to write his papers in topless bars. Cited on pages 507, 604, 605, and 610.

407 L. B. Kreuzer, Experimental measurement of the equivalence of active and passive gravitational mass, *Physical Review* **169**, pp. 1007–1012, 1968. With a clever experiment, he showed that the gravitational masses of fluorine and of bromine are equal. Cited on page 507.

408 A good and accessible book on the topic is David Blair & Geoff McNamara, *Ripples on a cosmic sea*, Allen & Unwin, 1997. Cited on page 508.

409 That bodies fall along geodesics, independently of their mass, the so-called weak equivalence principle, has been checked by many experiments, down to the 10^{-13} level. The most precise experiments use so-called torsion balances. See, for example, the website of the Eőt-Wash group at www.npl.washington.edu/eotwash/experiments/experiments.html. Cited on page 511.

410 So far, the experiments confirm that electrostatic and (strong) nuclear energy fall like matter to within one part in 10^8, and weak (nuclear) energy to within a few per cent. This is summarized in Ref. 414. Cited on page 512.

411 J. Soldner, *Berliner Astronomisches Jahrbuch auf das Jahr 1804*, 1801, p. 161. Cited on page 512.

412 See for example K. D. Olum, Superluminal travel requires negative energies, *Physical Review Letters* **81**, pp. 3567–3570, 1998, or M. Alcubierre, The warp drive: hyper-fast travel within general relativity, *Classical and Quantum Gravity* **11**, pp. L73–L77, 1994. See also Chris Van Den Broeck, A warp drive with more reasonable total energy requirements, *Classical and Quantum Gravity* **16**, pp. 3973–3979, 1999. Cited on page 515.

413 See the *Astronomical Almanac*, and its *Explanatory Supplement*, H.M. Printing Office, London and U.S. Government Printing Office, Washington, 1992. For the information about various time coordinates used in the world, such as barycentric coordinate time, the time at the barycentre of the solar system, see also the tycho.usno.navy.mil/systime.html web page. It also contains a good bibliography. Cited on page 516.

414 An overview is given in C. Will, *Theory and Experiment in Gravitational Physics*, chapter 14.3, Cambridge University Press, revised edition, 1993. (Despite being a standard reference, his view the role of tides and the role of gravitational energy within the principle of equivalence has been criticised by other researchers.) See also C. Will, *Was Einstein Right? – Putting General Relativity to the Test*, Oxford University Press, 1993. See also his paper arxiv.org/abs/gr-qc/9811036. Cited on pages 516, 535, and 643.

415 The calculation omits several smaller effects, such as rotation of the Earth and red-shift. For the main effect, see Edwin F. Taylor, 'The boundaries of nature: special and general relativity and quantum mechanics, a second course in physics' – Edwin F. Taylor's acceptance speech for the 1998 Oersted Medal presented by the American Association of Physics Teachers, 6 January 1998, *American Journal of Physics* **66**, pp. 369–376, 1998. Cited on page 517.

419 The equality was first tested with precision by R. von Eötvös, *Annalen der Physik & Chemie* **59**, p. 354, 1896, and by R. von Eötvös, V. Pekár, E. Fekete, Beiträge zum Gesetz der Proportionalität von Trägheit und Gravität, *Annalen der Physik 4, Leipzig* **68**, pp. 11–66, 1922. Eötvös found agreement to 5 parts in 10^9. More experiments were performed by P. G. Roll, R. Krotkow & R. H. Dicke, The equivalence of inertial and passive gravitational mass, *Annals of Physics (NY)* **26**, pp. 442–517, 1964, one of the most interesting and entertaining research articles in experimental physics, and by V. B. Braginsky & V. I. Panov, *Soviet Physics – JETP* **34**, pp. 463–466, 1971. Modern results, with errors less than one part in 10^{12}, are by Y. Su & al., New tests of the universality of free fall, *Physical Review* **D50**, pp. 3614–3636, 1994. Several experiments have been proposed to test the equality in space to less than one part in 10^{16}. Cited on pages 518 and 628.

GINSKY, C. M. CAVES & K. S. THORNE, Laboratory experiments to test relativistic gravity, *Physical Review D* **15**, pp. 2047–2068, 1992. Cited on page 527.

430 A. TARTAGLIA & M. L. RUGGIERO, Gravito-electromagnetism versus electromagnetism, *European Journal of Physics* **25**, pp. 203–210, 2004. Cited on page 527.

431 The original theoretical proposal is by S. M. KOPEIKIN, Testing the relativistic effect of the propagation of gravity by Very Long Baseline Interferometry, *Astrophysical Journal* **556**, pp. L1–L5, 2001, and the experimental data is E. B. FORMALONT & S. M. KOPEIKIN, The measurement of the light deflection from Jupiter: experimental results, *Astrophysical Journal* **598**, pp. 704–711, 2003. See also S. M. KOPEIKIN, The post-Newtonian treatment of the VLBI experiment on September 8, 2002, *Physics Letters A* **312**, pp. 147–157, 2003, or arxiv.org/abs/gr-qc/0212121. Several arguments against the claim were published, such as C. M. WILL, Propagation speed of gravity and the relativistic time delay, arxiv.org/abs/astro-ph/0301145, and S. SAMUEL, On the speed of gravity and the v/c corrections to the Shapiro time delay, arxiv.org/abs/astro-ph/0304006. The discussion went on, as shown in S. M. KOPEIKIN & E. B. FORMALONT, Aberration and the fundamental speed of gravity in the Jovian deflection experiment, *Foundations of Physics* **36**, pp. 1244–1285, 2006, preprint at arxiv.org/abs/astro-ph/0311063. Both sides claim to be right: the experiment claims to deduce the speed of gravity from the lack of a tangential component of the light deflection by the gravity of Jupiter, and the critical side claims that the speed of gravity does not enter in this measurement. If one compares the situation with analogous systems in transparent fluids or solids, which also show no tangential deflection component, the critical side has a point. Cited on pages 528 and 533.

432 The quadrupole formula is explained clearly in the text by Goenner. See Ref. 393. Cited on page 530.

493 Up to his death, Fred Hoyle defended his belief that the universe is static, e.g. in G. Burbidge, F. Hoyle & J. V. Narlikar, A different approach to cosmology, *Physics Today* **52**, pp. 38–44, 1999. This team has also written a book with the same title, published in 2000 by Cambridge University Press. Cited on page 589.

494 Stephen W. Hawking & G. F. R. Ellis, *The Large Scale Structure of Space-Time*, Cambridge University Press, Cambridge, 1973. Among other things, this reference text discusses the singularities of space-time, and their necessity in the history of the universe. Cited on pages 589, 622, and 652.

495 Augustine, *Confessions*, 398, writes: 'My answer to those who ask 'What was god doing before he made Heaven and Earth?' is not 'He was preparing Hell for people who pry into mysteries'. This frivolous retort has been made before now, so we are told, in order to evade the point of the question. But it is one thing to make fun of the questioner and another to find the answer. So I shall refrain from giving this reply. [...] But if before Heaven and Earth there was no time, why is it demanded what you [god] did then? For there was no "then" when there was no time.' (Book XI, chapter 12 and 13). Cited on page 591.

496 Stephen Hawking, *A Brief History of Time – From the Big Bang to Black Holes*, 1988. Reading this bestseller is almost a must for any physicist, as it is a frequent topic at dinner parties. Cited on page 591.

504 Entropy values for the universe have been discussed by Ilya Prigogine, *Is Future Given?*, World Scientific, 2003. This was his last book. For a different approach, see G. A. Mena Marugán & S. Carneiro, Holography and the large number hypothesis, arxiv.org/abs/gr-qc/0111034. This paper also repeats the often heard statement that the universe has an entropy that is much smaller than the theoretical maximum. The maximum is often estimated to be $10^{120}\,k$, whereas the actual value is 'estimated' to be $10^{100}\,k$. However, other authors give $10^{84}\,k$. In 1974, Roger Penrose also made statements about the entropy of the universe. Cited on page 599.

CHALLENGE HINTS AND SOLUTIONS

Challenge 612, page 401: A cone or a hyperboloid also looks straight from all directions, provided the positioning is correct. One thus needs not only to turn the object, but also to displace it. The best method to check planarity is to use interference between an arriving and a departing coherent beam of light. If the fringes are straight, the surface is planar. (How do you ensure the wave front of the light beam is planar?)

Challenge 613, page 401: A fraction of infinity is still infinite.

Challenge 614, page 403: The time at which the Moon Io enters the shadow in the second measurement occurs about 1000 s later than predicted from the first measurement. Since the Earth is about $3 \cdot 10^{11}$ m further away from Jupiter and Io, we get the usual value for the speed of light.

Challenge 615, page 403: To compensate for the aberration, the telescope has to be inclined *along* the direction of motion of the Earth; to compensate for parallaxis, *against* the motion.

Challenge 616, page 403: Otherwise the velocity sum would be larger than c.

Challenge 617, page 403: The drawing shows it. Observer, Moon and Sun form a triangle. When the Moon is half full, the angle at the Moon is a right angle. Thus the distance ration can be determined, though not easily, as the angle at the observer is very close to a right angle as well.

Challenge 618, page 404: There are Cat's-eyes on the Moon deposited there during the Apollo and Lunokhod missions. They are used to reflect laser 35 ps light pulses sent there through telescopes. The timing of the round trip then gives the distance to the Moon. Of course, absolute distance is not know to high precision, but the variations are. The thickness of the atmosphere is the largest source of error. See the www.csr.utexas.edu/mlrs and ilrs.gsfc.nasa.gov websites.

Challenge 619, page 404: Fizeau used a mirror about 8.6 km away. As the picture shows, he only had to count the teeth of his cog-wheel and measure its rotation speed when the light goes in one direction through one tooth and comes back to the next.

Challenge 620, page 405: The time must be shorter than $T = l/c$, in other words, shorter than 30 ps; it was a *gas* shutter, not a solid one. It was triggered by a red light pulse (shown in the photograph) timed by the pulse to be photographed; for certain materials, such as the used gas, strong light can lead to bleaching, so that they become transparent. For more details about the shutter and its neat trigger technique, see the paper by the authors. For even faster shutters, see also the discussion on page 1492.

Challenge 621, page 405: Just take a photograph of a lightning while moving the camera horizontally. You will see that a lightning is made of several discharges; the whole shows that lightning is much slower than light.

If lightning moved only nearly as fast as light itself, the Doppler effect would change it colour depending on the angle at which we look at it, compared to its direction of motion. A nearby lightning would change colour from top to bottom.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

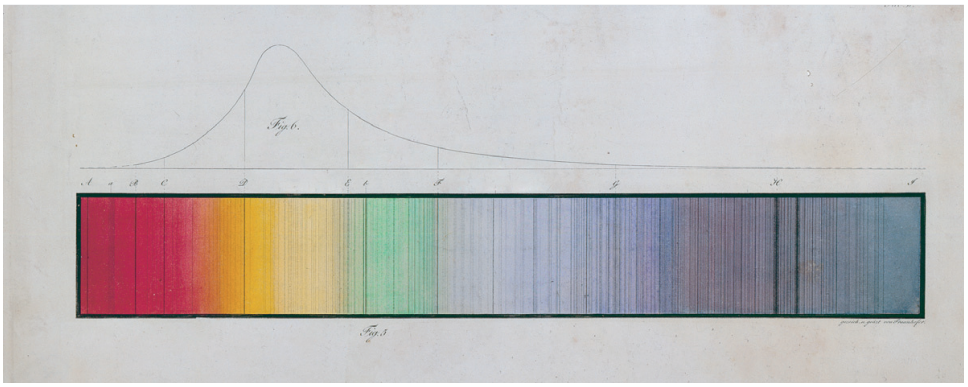

FIGURE 317 The original lines published by Fraunhofer (© Fraunhofer Gesellschaft)

Challenge 622, page 406: The fastest lamps were subatomic particles, such as muons, which decay by emitting a photon, thus a tiny flash of light. However, also some stars emit fasts jets of matter, which move with speeds comparable to that of light.

Challenge 623, page 407: The speed of neutrinos is the same as that of light to 9 decimal digits, since neutrinos and light were observed to arrive together, within 12 seconds of each other, after a trip of 170 000 light years from a supernova explosion.

Ref. 323

Challenge 625, page 411: This is best discussed by showing that other possibilities make no sense.

Challenge 626, page 411: The spatial coordinate of the event at which the light is reflected is $c(k^2-1)T/2$; the time coordinate is $(k^2+1)T/2$. Their ratio must be v. Solving for k gives the result.

Challenge 628, page 412: The motion of radio waves, infrared, ultraviolet and gamma rays is also unstoppable. Another past suspect, the neutrino, has been found to have mass and to be thus in principle stoppable. The motion of gravity is also unstoppable.

Challenge 630, page 414: $\lambda_R/\lambda_S = \gamma$.

Challenge 631, page 414: To change from bright red (650 nm) to green (550 nm), $v = 0.166c$ is necessary.

Challenge 632, page 414: People measure the shift of spectral lines, such as the shift of the so-called Lyman-α line of hydrogen, that is emitted (or absorbed) when a free electron is captured (or ejected) by a proton. It is one of the famous Fraunhofer lines.

Page 1041

Challenge 633, page 414: The speeds are given by

$$v/c = \frac{(z+1)^2-1}{(z+1)^2+1} \tag{425}$$

which implies $v(z=-0.1) = 31\,\mathrm{Mm/s} = 0.1c$ *towards* the observer and $v(z=5) = 284\,\mathrm{Mm/s} = 0.95c$ *away* from the observer.

A red-shift of 6 implies a speed of $0.96c$; such speeds appear because, as we will see in the section of general relativity, far away objects recede from us. And high red-shifts are observed only for objects which are extremely far from Earth, and the faster the further they are away. For a red-shift of 6 that is a distance of several thousand million light years.

Challenge 634, page 414: No Doppler effect is seen for a distant observer at rest with respect to the large mass. In other cases there obviously is a Doppler effect, but it is not due to the deflection.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 635, page 415: Sound speed is not invariant of the speed of observers. As a result, the Doppler effect for sound even confirms – within measurement differences – that time is the *same* for observers moving against each other.

Challenge 638, page 416: Inside colour television tubes (they use higher voltages than black and white ones), electrons are described by $v/c \approx \sqrt{2 \cdot 30/511}$ or $v \approx 0.3c$.

Challenge 639, page 416: If you can imagine this, publish it. Readers will be delighted to hear the story.

Challenge 641, page 417: The connection between observer invariance and limit property seems to be generally valid in nature, as shown in section 55. However, a complete and airtight argument is not yet at hand. If you have one, publish it!

Page 1458

Challenge 644, page 418: If the speed of light is the same for all observers, no observer can pretend to be more at rest than another (as long as space-time is flat), because there is no observation from electrodynamics, mechanics or another part of physics that allows to make the statement.

Challenge 647, page 421: Redrawing Figure 230 on page 410 for the other observer makes the point.

Challenge 648, page 421: The human value is achieved in particle accelerators; the value in nature is found in cosmic rays of the highest energies.

Challenge 649, page 422: The set of events behaves like a manifold, because it behaves like a four-dimensional space: it has infinitely many points around any given starting point, and distances behave as we are used to, limits behave as we are used to. It differs by one added dimension, and by the sign in the definition of distance; thus, properly speaking, it is a Riemannian manifold.

Challenge 650, page 423: Infinity is obvious, as is openness. Thus the topology equivalence can be shown by imagining that the manifold is made of rubber and wrapped around a sphere.

Challenge 651, page 424: The light cone remains unchanged; thus causal connection as well.

Challenge 652, page 424: In such a case, the division of space-time around an inertial observer into future, past and elsewhere would not hold any more, and the future could influence the past (as seen from another observer).

Challenge 656, page 427: The ratio predicted by naive reasoning is $(1/2)^{(}6.4/2.2) = 0.13$.

Challenge 657, page 427: The time dilation factor for $v = 0.9952c$ is 10.2, giving a proper time of 0.62 μs; thus the ratio predicted by special relativity is $(1/2)^{(}0.62/2.2) = 0.82$.

Challenge 658, page 428: Send a light signal from the first clock to the second clock and back. Take the middle time between the departure and arrival, and then compare it with the time at the reflection. Repeat this a few times. See also Figure 230.

Challenge 661, page 428: Hint: think about different directions of sight.

Challenge 662, page 429: Not with present experimental methods.

Challenge 664, page 429: Hint: be careful with the definition of 'rigidity'.

Challenge 666, page 430: While the departing glider passes the gap, the light cannot stay on at any speed, if the glider is shorter than the gap. This is strange at first sight, because the glider does not light the lamp even at high speeds, even though in the frame of the glider there is contact at both ends. The reason is that in this case there is not enough time to send the signal to the battery that contact is made, so that the current cannot start flowing.

Assume that current flows with speed u, which is of the order of c. Then, as Dirk Van de Moortel showed, the lamp will go off if the glider length l_{glider} and the gap length l_{gap} obey $l_{\text{glider}}/l_{\text{gap}} < \gamma(u+v)/u$. See also the cited reference.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

For a glider approaching the gap and the lamp, the situation is different: a glider shorter than the gap *can* keep the lamp on all the time, as pointed out by S.R. Madhu Rao.

Why are the debates often heated? Some people will (falsely) pretend that the problem is unphysical; other will say that Maxwell's equations are needed. Still others will say that the problem is absurd, because for larger lengths of the glider, the on/off answer depends on the precise speed value. However, this actually is the case in this situation.

Challenge 667, page 430: Yes, the rope breaks; in accelerated cars, distance changes, as shown later on in the text.

Challenge 668, page 430: The submarine will sink. The fast submarine will even be heavier, as his kinetic energy adds to his weight. The contraction effect would make it lighter, as the captain says, but by a smaller amount. The total weight – counting upwards as positive – is given by $F = -mg(\gamma - 1/\gamma)$.

Challenge 669, page 430: A relativistic submarine would instantly melt due to friction with the water. If not, it would fly of the planet because it moves faster than the escape velocity. And produce several other disasters.

Challenge 670, page 431: The question confuses observation of Lorentz contraction and its measurement. A relativistic pearl necklace does get shorter, but the shortening can only be measured, not photographed. The measured sizes of the pearls are flattened ellipsoids relativistic speeds. The observed necklace consists of overlapping spheres.

Challenge 673, page 434: Yes, ageing in a valley is slowed compared to mountain tops. However, the proper sensation of time is not changed. The reason for the appearance of grey hair is not known; if the timing is genetic, the proper time at which it happens is the same in either location.

Challenge 674, page 435: There is no way to put an observer at the specified points. Proper velocity can only be defined for observers, i.e., for entities which can carry a clock. That is not the case for images.

Challenge 675, page 435: Just use plain geometry to show this.

Challenge 676, page 435: Most interestingly, the horizon can easily move faster than light, if you move your head appropriately, as can the end of the rainbow.

Challenge 679, page 439: Relativity makes the arguments of challenge 161 watertight.

Challenge 684, page 441: The lower collision in Figure 254 shows the result directly, from energy conservation. For the upper collision the result also follows, if one starts from momentum conservation $\gamma mv = \Gamma MV$ and energy conservation $(gamma + 1)m = \Gamma M$.

Challenge 686, page 443: Annihilation of matter and antimatter.

Challenge 693, page 446: Just turn the left side of Figure 257 a bit in anti-clockwise direction.

Challenge 694, page 447: In collisions between relativistic charges, part of the energy is radiated away as light, so that the particles effectively lose energy.

Challenge 695, page 448: Probably not, as all relations among physical quantities are known now. However, you might check for yourself; one might never know. It is worth to mention that the maximum force in nature was discovered (in this text) after remaining hidden for over 80 years.

Challenge 696, page 450: Write down the four-vectors U' and U and then extract v' as function of v and the relative coordinate speed V. Then rename the variables.

Challenge 697, page 450: Any motion with light speed.

Challenge 698, page 450: $b^0 = 0$, $b^i = \gamma^2 a_i$.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 701, page 452: For ultrarelativistic particles, like for massless particles, one has $E = pc$.

Challenge 702, page 452: Hint: evaluate P_1 and P_2 in the rest frame of one particle.

Challenge 703, page 452: Use the definition $\boldsymbol{F} = \mathrm{d}\boldsymbol{p}/\mathrm{d}t$ and the relation $\boldsymbol{K}U = 0 = \boldsymbol{f}v - \mathrm{d}E/\mathrm{d}t$ valid for rest-mass preserving forces.

Challenge 707, page 454: Yes, one can see such an object: the searchlight effect and the Doppler effect do not lead to invisibility. However, part of the object, namely the region rotating away from the observer, may become very dark.

Challenge 731, page 462: The energy contained in the fuel must be comparable to the rest mass of the motorbike, multiplied by c^2. Since fuel contains much more mass than energy, that gives a big problem.

Challenge 733, page 463: Constant acceleration and gravity are similar in their effects, as discussed in the section on general relativity.

Challenge 739, page 465: Yes, it is true.

Challenge 740, page 465: It is flat, like a plane.

Challenge 742, page 466: Yes; however, the effect is minimal and depends on the position of the Sun. In fact, what is white at one height is not white at another.

Challenge 744, page 466: Locally, light always moves with speed c.

Challenge 745, page 467: Away from Earth, g decreases; it is effectively zero over most of the distance.

Challenge 746, page 468: Light is necessary to determine distance *and* to synchronize clocks; thus there is no way to measure the speed of light from one point to another alone. The reverse motion needs to be included. However, some statements on the one-way speed of light can still be made (see math.ucr.edu/home/baez/physics/Relativity/SR/experiments.html). All experiments on the one-way speed of light performed so far are consistent with an isotropic value that is equal to the two-way velocity. However, no experiment is able to rule out a group of theories in which the one-way speed of light is anisotropic and thus different from the two-way speed. All theories from this group have the property that the *round-trip* speed of light is isotropic in any inertial frame, but the *one-way* speed is isotropic only in a preferred 'ether' frame. In all of these theories, in all inertial frames, the effects of slow clock transport exactly compensate the effects of the anisotropic one-way speed of light. All these theories are experimentally indistinguishable from special relativity. In practice, therefore, the one-way speed of light has been measured and is constant. But a small option remains.

Challenge 747, page 468: See the cited reference. The factor 2 was forgotten there; can you deduce it?

Challenge 750, page 470: Though there are many publications pretending to study the issue, there are also enough physicists who notice the impossibility. Measuring a variation of the speed of light is not much far from measuring the one way speed of light: it is not possible. However, the debates on the topic are heated; the issue will take long to be put to rest.

Challenge 751, page 471: The inverse square law of gravity does not comply with the maximum speed principle; it is not clear how it changes when one changes to a moving observer.

Challenge 752, page 476: Take a surface moving with the speed of light, or a surface defined with a precision smaller than the Planck length.

Challenge 753, page 481: Also shadows do not remain parallel in curved surfaces. forgetting this leads to strange mistakes: many arguments allegedly 'showing' that men have never been on the moon neglect this fact when they discuss the photographs taken there.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 754, page 482: If you find one, publish it and then send it to the author of this text.

Challenge 756, page 488: If so, publish it; then send it to the author of this text.

Challenge 757, page 490: For example, it is possible to imagine a surface that has such an intricate shape that it will pass all atoms of the universe at almost the speed of light. Such a surface is not physical, as it is impossible to imagine observers on all its points that move in that way all at the same time.

Challenge 759, page 491: Many do not believe the limits yet; so any proposed counter-example or any additional paradox is worth a publication.

Challenge 761, page 495: If so, publish it; then send it to the author of this text.

Challenge 764, page 496: If so, publish it; then send it to the author of this text.

Challenge 766, page 499: They are accelerated upwards.

Challenge 767, page 499: In everyday life, (a) the surface of the Earth can be taken to be flat, (b) the vertical curvature effects are negligible, and (c) the lateral length effects are negligible.

Challenge 771, page 500: For a powerful bus, the acceleration is $2\,\mathrm{m/s^2}$; in 100 m of acceleration, this makes a relative frequency change of $2.2 \cdot 10^{-15}$.

Challenge 772, page 500: Yes, light absorption and emission are always lossless conversions of energy into mass.

Challenge 775, page 501: For a beam of light, in both cases the situation is described by an environment in which masses 'fall' against the direction of motion. If the Earth and the train walls were not visible – for example if they were hidden by mist – there would not be any way to determine by experiment which situation is which. Or again, if an observer would be enclosed in a box, he could not distinguish between constant acceleration or constant gravity. (Important: this impossibility only applies if the observer has negligible size!)

Challenge 781, page 503: Both fall towards the centre of the Earth. Orbiting particles are also in free fall; their relative distance changes as well, as explained in the text.

Challenge 784, page 505: Such a graph would need four or even 5 dimensions.

Challenge 786, page 506: The energy due to the rotation can be neglected compared with all other energies in the problem.

Challenge 796, page 512: Different nucleons, different nuclei, different atoms and different molecules have different percentages of binding energies relative to the total mass.

Challenge 798, page 513: In free fall, the bottle and the water remain at rest with respect to each other.

Challenge 799, page 514: Let the device fall. The elastic rubber then is strong enough to pull the ball into the cup. See M. T. Westra, Einsteins verjaardagscadeau, *Nederlands tijdschrift voor natuurkunde* **69**, p. 109, April 2003. The original device also had a spring connected in series to the rubber.

Challenge 800, page 514: Apart the chairs and tables already mentioned, important anti-gravity devices are suspenders, belts and plastic bags.

Challenge 806, page 514: They use a spring scale, and measure the oscillation time. From it they deduce their mass.

Challenge 807, page 514: The apple hits the wall after about half an hour.

Challenge 811, page 515: With $\hbar$ as smallest angular momentum one get about 100 Tm.

Challenge 812, page 515: No. The diffraction of the beams does not allow it. Also quantum theory makes this impossible; bound states of massless particles, such as photons, are not stable.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 814, page 517: The orbital radius is 4.2 Earth radii; that makes *c.* 38 μs every day.

Challenge 815, page 517: To be honest, the experiments are not consistent. They assume that some other property of nature is constant – such as atomic size – which in fact also depends on *G*. More on this issue on page 630.

Challenge 816, page 517: Of course other spatial dimensions could exist which can be detected only with the help of measurement apparatuses. For example, hidden dimensions could appear at energies not accessible in everyday life.

Challenge 826, page 524: Since there is no negative mass, gravitoelectric fields cannot be neutralized. In contrast, electric fields can be neutralized around a metallic conductor with a Faraday cage.

Challenge 839, page 533: One needs to measure the timing of pulses which cross the Earth at different gravitational wave detectors on Earth.

Challenge 858, page 540: No; a line cannot have intrinsic curvature. A torus is indeed intrinsically curved; it cannot be cut open to a flat sheet of paper.

Challenge 880, page 549: The trace of the Einstein tensor is the negative of the Ricci scalar; it is thus the negative of the trace of the Ricci tensor.

Challenge 897, page 560: Indeed, in general relativity gravitational energy cannot be localized in space, in contrast to what one expects and requires from an interaction.

Challenge 910, page 568: There is a good chance that some weak form of a jet exists; but a detection will not be easy.

Challenge 914, page 574: Speed is measured with the Doppler effect, usually by looking at the Lyman-alpha line. Distance is much more difficult to explain. Measuring distances is a science on its own, depending on whether one measures distances of stars in the galaxy, to other galaxies, or to quasars. Any book on astronomy or astrophysics will tell more.

Challenge 917, page 580: The rabbit observes that all other rabbits seem to move away from him.

Challenge 923, page 585: Stand in a forest in winter, and try to see the horizon. If the forest is very deep, you hit tree trunks in all directions. If the forest is finite in depth, you have chance to see the horizon.

Challenge 939, page 599: The universe does not allow observation from outside. It thus has no state properties.

Challenge 944, page 602: Flattening due to rotation requires other masses to provide the background against which the rotation takes place.

Challenge 974, page 615: This happens in the same way that the static electric field comes out of a charge. In both cases, the transverse fields do not get out, but the longitudinal fields do. Quantum theory provides the deeper reason. Real radiation particles, which are responsible for free, transverse fields, cannot leave a black hole because of the escape velocity. However, virtual particles can, as their speed is not bound by the speed of light. All static, longitudinal fields are produced by virtual particles. In addition, there is a second reason. Classical field can come out of a black hole because for an outside observer everything that constitues the black hole is continuously falling, and no constituent has actually crossed the horizon. The field sources thus are not yet out of reach.

Challenge 978, page 615: The description says it all. A visual impression can be found in the room on black holes in the 'Deutsches Museum' in München.

Challenge 987, page 621: Any device that uses mirrors requires electrodynamics; without electrodynamics, mirrors are impossible.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 989, page 624: The hollow Earth theory is correct if usual distances are consistently changed according to $r_{\text{he}} = R_{\text{Earth}}^2/r$. This implies a quantum of action that decreases towards the centre of the hollow sphere. Then there is no way to prefer one description over the other, except for reasons of simplicity.

Third Part

Light, Charges and Brains

In our quest to learn how things move,
the experience of hiking and other motion
leads us to discover that images are produced by charges,
that charges move, accumulate and interact,
and that there is a smallest charge in nature.
We understand what love has to do with magnets and amber,
why the brain is such an interesting device,
and what distinguishes a good from a bad lie.

Chapter 23

LIQUID ELECTRICITY, INVISIBLE FIELDS AND MAXIMUM SPEED

What is light? The study of relativity left us completely in the dark, even though we had embarked in it precisely to find an answer to that question. True, we have learned how the motion of light compares with that of objects. We also learned that light is a moving entity that cannot be stopped; but we haven't learned anything about its nature. And what is contact? We still do not know. The answer to these long-standing questions emerges only from the study of those types of motion that are *not* related to gravitation, such as the ways magicians levitate objects.

Page 182

Revisiting the list of motors found in this world, we remark that gravitation hardly describes any of them. Neither the motion of sea waves, fire and earthquakes, nor that of a gentle breeze is caused by gravity. The same applies to the motion of muscles.* Have you ever listened to your own heart beat with a stethoscope? Without having done so, you cannot claim to have experienced the mystery of motion. Your heart has about 3000 million beats in your lifetime. Then it stops.

Challenge 994 e

It was one of the most astonishing discoveries of science that heart beats, sea waves and most other cases of everyday motion, as well as the nature of light itself, are connected to observations made thousands of years ago using two strange stones. These stones show that all those examples of motion that are called *mechanical* in everyday life are, without exception, of *electrical* origin.

In particular, the solidity, the softness and the impenetrability of matter are due to internal electricity; also the emission of light is an electrical process. As these aspects are part of everyday life, we will leave aside all complications due to gravity and curved space-time. The most productive way to study electrical motion is to start, as in the case of gravity, with those types of motion which are generated without any contact between the bodies involved.

Ref. 557

Amber, lodestone and mobile phones

The story of electricity starts with trees. Trees have a special relation to electricity. When a tree is cut, a viscous resin appears. With time it solidifies and, after millions of years, it forms *amber*. When amber is rubbed with a cat fur, it acquires the ability to attract small objects, such as saw dust or pieces of paper. This was already known to Thales of Miletus, one of the original seven sages, in the sixth century BCE. The same observation can be made with many other polymer combinations, for example with combs and hair,

* The photograph of a circular rainbow on page 665 was taken in 2006 from the Telstra Tower in Canberra (© Oat Vaiyaboon).

FIGURE 318 Objects surrounded by fields: amber (c. 1 cm), lodestone (c. 1 cm) and mobile phone (c. 10 cm) (© Philips)

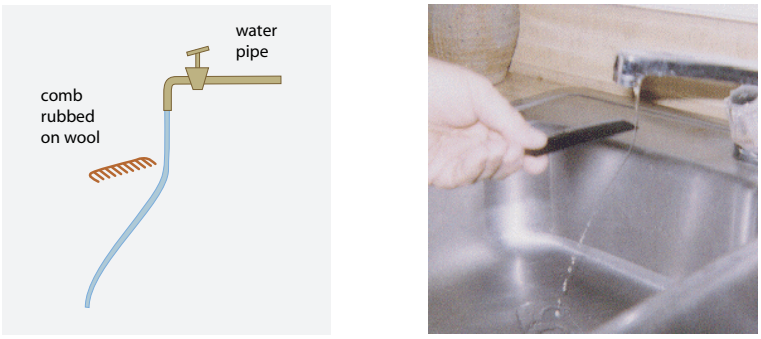

FIGURE 319 How to amaze kids, especially in dry weather (photo © Robert Fritzius)

with soles of the shoe on carpets, and with a TV screen and dust. Children are always surprised by the effect, shown in Figure 319, that a comb rubbed on wool has on running tap water. The same effect can be produced with an air-filled rubber balloon rubbed on wool. Another interesting effect can be observed when a rubbed comb is put near a burning candle. (Can you imagine what happens?)

Challenge 995 ny

Another part of the story of electricity involves an iron mineral found in certain caves around the world, e.g. in a region (still) called Magnesia in the Greek province of Thessalia, and in some regions in central Asia. When two stones of this mineral are put near each other, they attract or repel each other, depending on their relative orientation. In addition, these stones attract objects made of cobalt, nickel or iron.

Today we also find various small objects in nature with more sophisticated properties, as shown in Figure 318. Some objects enable you to switch on a television, others unlock car doors, still others allow you to talk with far away friends.

All these observations show that in nature there are situations where bodies exert influence on others *at a distance*. The space surrounding a body exerting such an influence is said to contain a field. A *(physical) field* is thus an entity that manifests itself by accelerating other bodies in its region of space. A field is some 'stuff' taking up space. Experiments show that fields have no mass. The field surrounding the mineral found in Magne-

sia is called a *magnetic field* and the stones are called *magnets*.* The field around amber – called ἤλεκτρον in Greek, from a root meaning 'brilliant, shining' – is called an *electric field*. The name is due to a proposal by the famous English part-time physicist William Gilbert (1544–1603) who was physician to Queen Elizabeth I. Objects surrounded by a permanent electric field are called *electrets*. They are much less common than magnets; among others, they are used in certain loudspeaker systems.**

The field around a mobile phone is called a *radio* field or, as we will see later, an *electromagnetic* field. In contrast to the previous fields, it oscillates over time. We will find out later that many other objects are surrounded by such fields, though these are often very weak. Objects that emit oscillating fields, such as mobile phones, are called radio transmitters or radio emitters.

Fields influence bodies over a distance, without any material support. For a long time, this was rarely found in everyday life, as most countries have laws to restrict machines that use and produce such fields. The laws require that for any device that moves, produces sound, or creates moving pictures, the fields need to remain inside them. For this reason a magician moving an object on a table via a hidden magnet still surprises and entertains his audience. To feel the fascination of fields more strongly, a deeper look into a few experimental results is worthwhile.

How can one make lightning?

Everybody has seen a lightning flash or has observed the effect it can have on striking a tree. Obviously lightning is a moving phenomenon. Photographs such as that of Figure 320 show that the tip of a lightning flash advance with an average speed of around 600 km/s. But *what* is moving? To find out, we have to find a way of making lightning for ourselves.

In 1995, the car company General Motors accidentally rediscovered an old and simple method of achieving this. Their engineers had inadvertently built a spark generating mechanism into their cars; when filling the petrol tank, sparks were generated, which sometimes lead to the explosion of the fuel. They had to recall 2 million vehicles of its Opel brand. Ref. 559

* A pretty book about the history of magnetism and the excitement it generates is JAMES D. LIVINGSTON, *Driving Force – the Natural Magic of Magnets*, Harvard University Press, 1996.

** The Kirlian effect, which allows one to make such intriguingly beautiful photographs, is due to a time-varying electric field.

TABLE 58 Some observed magnetic fields

OBSERVATION	MAGNETIC FIELD
Lowest measured magnetic field (e.g., fields of the Schumann resonances)	1 fT
Magnetic field produced by brain currents	0.1 pT to 3 pT
Magnetic field produced by single muscle action	1 pT
Intergalactic magnetic fields	1 pT to 10 pT
Magnetic field in the human chest, due to heart currents	100 pT
Magnetic field of our galaxy	0.5 nT
Magnetic field due to solar wind	0.2 to 80 nT
Magnetic field directly below high voltage power line	0.1 to 1 μT
Magnetic field of Earth	20 to 70 μT
Magnetic field inside home with electricity	0.1 to 100 μT
Magnetic field near mobile phone	100 μT
Magnetic field that influences visual image quality in the dark	100 μT
Magnetic field near iron magnet	100 mT
Solar spots	1 T
Magnetic fields near high technology permanent magnet	max 1.3 T
Magnetic fields that produces sense of coldness in humans	5 T or more
Magnetic fields in particle accelerator	10 T
Maximum static magnetic field produced with superconducting coils	22 T
Highest static magnetic fields produced in laboratory, using hybrid magnets	45 T
Highest *pulsed* magnetic fields produced without coil destruction	76 T
Pulsed magnetic fields produced, lasting about 1 μs, using imploding coils	1000 T
Field of white dwarf	10^4 T
Fields in petawatt laser pulses	30 kT
Field of neutron star	from 10^6 T to 10^{11} T
Quantum critical magnetic field	4.4 GT
Highest field ever measured, on magnetar and soft gamma repeater SGR-1806-20	$0.8 \text{ to } 1 \cdot 10^{11}$ T
Field near nucleus	1 TT
Maximum (Planck) magnetic field	$2.2 \cdot 10^{53}$ T

What had the engineers done wrong? They had unwittingly copied the conditions for a electrical device which anyone can build at home and which was originally invented by William Thomson:* the *Kelvin generator*. Repeating his experiment today, we would

* William Thomson (1824–1907), important Irish Unionist physicist and professor at Glasgow University. He worked on the determination of the age of the Earth, showing that it was much older than 6000 years, as several sects believed. He strongly influenced the development of the theory of magnetism and electricity, the description of the aether and thermodynamics. He propagated the use of the term 'energy' as it is

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

take two water taps, four empty bean or coffee cans, of which two have been opened at both sides, some nylon rope and some metal wire. Ref. 560

Putting this all together as shown in Figure 321, and letting the water flow, we find a strange effect: large sparks periodically jump between the two copper wires at the point where they are nearest to each other, giving out loud bangs. Can you guess what condition

used today, instead of the confusing older terms. He was one of the last scientists to propagate mechanical analogies for the explanation of phenomena, and thus strongly opposed Maxwell's description of electromagnetism. It was mainly for this reason that he failed to receive a Nobel Prize. He was also one of the minds behind the laying of the first transatlantic telegraphic cable. Victorian to his bones, when he was knighted, he chose the name of a small brook near his home as his new name; thus he became Baron Kelvin of Largs. Therefore the unit of temperature obtained its name from a small Scottish river.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

for the flow has to be realized for this to work? And what did Opel do to repair the cars they recalled? Challenge 996 s

If we stop the water flowing just before the next spark is due, we find that both buckets are able to attract sawdust and pieces of paper. The generator thus does the same that rubbing amber does, just with more bang for the buck(et). Both buckets are surrounded by electric fields. The fields increase with time, until the spark jumps. Just after the spark, the buckets are (almost) without electric field. Obviously, the flow of water somehow builds up an entity on each bucket; today we call this *electric charge*. Charge can flow in metals and, when the fields are high enough, through air. We also find that the two buckets are surrounded by two different types of electric fields: bodies that are attracted by one bucket are repelled by the other.

All experiments confirm that there are *two* types of charges. The US politician and part-time physicist Benjamin Franklin (1706–1790) called the electricity created on a glass rod rubbed with a dry cloth *positive*, and that on a piece of amber *negative*. (Previously, the two types of charges were called 'vitreous' and 'resinous'.) Bodies with charges of the same sign repel each other, bodies with opposite charges attract each other; charges of opposite sign flowing together cancel each other out.*

Flows take time. How fast is electricity? A simple way to measure the speed of electricity is to produce a small spark at one end of a long wire, and to observe how long it takes until the spark appears at the other end of the wire. In practice, the two sparks are almost simultaneous; the speed one measures is much higher than everything else we observe in our environment. How can we measure the time nevertheless? And why did different researchers get very different speed values in this experiment? Challenge 997 s

In summary, electric fields start at bodies, provided they are charged. Charging can be achieved by rubbing and similar processes. Charge can flow: it is then called an electric *current*. The worst conductors of current are polymers; they are called *insulators* or *dielectrics*. A charge put on an insulator remains at the place where it was put. In contrast, metals are good conductors; a charge placed on a conductor spreads all over its surface. The best conductors are silver and copper. This is the reason that at present, after two hundred years of use of electricity, the highest concentration of copper in the world is below the surface of Manhattan.

Of course, one has to check whether natural lightning is actually electrical in origin. In 1752, experiments performed in France, following a suggestion by Benjamin Franklin, published in London in 1751, showed that one can indeed draw electricity from a thunderstorm via a long rod.** These French experiments made Franklin famous worldwide; they were also the start of the use of lightning rods all over the world. Later, Franklin had a lightning rod built through his own house, but of a somewhat unusual type, as shown in Figure 322. Can you guess what it did in his hall during bad weather, all parts being made of metal? (Do not repeat this experiment; the device can kill.) Ref. 561 Challenge 998 s

* In fact, there are many other ways to produces sparks or even *arcs*, i.e., sustained sparks; there is even a complete subculture of people who do this as a hobby at home. Those who have a larger budget do it professionally, in particle accelerators. See the www.kronjaeger.com/hv website.

** The details of how lightning is generated and how it propagates are still a topic of research. An introduction is given on page 776.

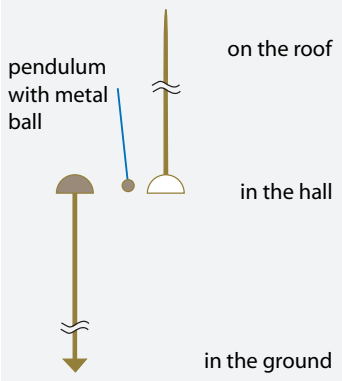

FIGURE 322 Franklin's personal lightning rod

Electric charge and electric fields

If all experiments with charge can be explained by calling the two charges positive and negative, the implication is that some bodies have more, and some less charge than an uncharged, *neutral* body. Electricity thus only flows when two differently charged bodies are brought into contact. Now, if charge can flow and accumulate, we must be able to somehow measure its amount. Obviously, the *amount* of charge on a body, usually abbreviated q, is defined via the influence the body, say a piece of sawdust, feels when subjected to a field. Charge is thus defined by comparing it to a standard reference charge. For a charged body of mass m accelerated in a field, its charge q is determined by the relation

$$\frac{q}{q_{\text{ref}}} = \frac{ma}{m_{\text{ref}}a_{\text{ref}}} \,, \tag{426}$$

i.e., by comparing it with the acceleration and mass of the reference charge. This definition reflects the observation that mass alone is not sufficient for a complete characterization of a body. For a full description of motion we need to know its electric charge; charge is therefore the second intrinsic property of bodies that we discover in our walk.

Nowadays the unit of charge, the *coulomb*, is defined through a standard flow through metal wires, as explained in Appendix C. This is possible because all experiments show that charge is conserved, that it flows, that it flows continuously and that it can accumulate. Charge thus behaves like a fluid substance. Therefore we are forced to use for its description a scalar quantity q, which can take positive, vanishing, or negative values.

In practice, electric charge is measured with *electrometers*. A few such devices are shown in Figure 323. Experiments with these devices first of all conform that charges flow and accumulate. More precisely, all experiments show that charges are conserved. In other words, if the electric charge of a physical system changes, the reason always is that charge is flowing into or out of the system. This can be checked easily with two metal pots connected to two electrometers, as shown in Figure 324.

Ref. 562

The main experimental properties of electric charge that are discovered when experimenting with electrometers are listed in Table 59. These properties describe the behaviour electrical charge values. However, as in the case of all previously encountered

Total charge of positive (or negative) sign observed in universe	$10^{62\pm2}$ C
Total charge observed in universe	0 C

to be only approximate. More precise experiments will require a revision of several properties. However, one observation remains: no counter-example to charge conservation has as yet been observed.

A charged object brought near a neutral one polarizes it. *Electrical polarization* is the separation of the positive and negative charges in a body. For this reason, even neutral objects, such as hair, can be attracted to a charged body, such as a comb. Generally, both insulators and conductors can be polarized; this occurs for whole stars down to single molecules.

Attraction is a form of acceleration. Experiments show that the entity that accelerates charged bodies, the *electric field*, behaves like a small arrow fixed at each point $\boldsymbol{x}$ in space; its length and direction do not depend on the observer. In short, the electric field $\boldsymbol{E}(\boldsymbol{x})$ is a *vector* field. Experiments show that it is best defined by the relation

$$q\boldsymbol{E}(\boldsymbol{x}) = m\boldsymbol{a}(\boldsymbol{x}) \tag{427}$$

taken at every point in space $\boldsymbol{x}$. The definition of the electric field is thus based on how it *moves* charges.* The field is measured in multiples of the unit N/C or V/m.

Field of a GSM antenna at 90 m	0.5 V/m
Field inside a typical home	1 to 10 V/m
Field of a 100 W bulb at 1 m distance	50 V/m
Ground field in Earth's atmosphere	100 to 300 V/m
Field inside thunder clouds	up to over 100 kV/m
Maximum electric field in air before sparks appear	1 to 3 MV/m
Electric fields in biological membranes	10 MV/m
Electric fields inside capacitors	up to 1 GV/m
Electric fields in petawatt laser pulses	10 TV/m
Electric fields in U^{91+} ions, at nucleus	1 EV/m
Maximum practical electric field in vacuum, limited by electron pair production	1.3 EV/m
Maximum possible electric field in nature (corrected Planck electric field)	$2.4 \cdot 10^{61}$ V/m

To describe the motion due to electricity completely, we need a relation explaining how charges *produce* electric fields. This relation was established with precision (but not for the first time) by Charles-Augustin de Coulomb on his private estate, during the French Revolution.* He found that around any small-sized or any spherical charge Q *at rest* there is an electric field. At a position $\boldsymbol{r}$, the electric field $\boldsymbol{E}$ is given by

$$\boldsymbol{E}(\boldsymbol{r}) = \frac{1}{4\pi\varepsilon_0}\frac{Q}{r^2}\frac{\boldsymbol{r}}{r} \quad \text{where} \quad \frac{1}{4\pi\varepsilon_0} = 9.0\,\text{GV m/C}\,. \tag{428}$$

Later we will extend the relation for a charge in motion. The bizarre proportionality constant, built around the so-called *permittivity of free space* ε_0, is due to the historical way the unit of charge was defined first.** The essential point of the formula is the decrease of the field with the square of the distance; can you imagine the origin of this dependence? Challenge 1002 s

* Charles-Augustin de Coulomb (b. 1736 Angoulême, d. 1806 Paris), French engineer and physicist. His careful experiments on electric charges provided a firm basis for the study of electricity.

** Other definitions of this and other proportionality constants to be encountered later are possible, leading to *unit systems* different from the SI system used here. The SI system is presented in detail in Appendix C. Among the older competitors, the Gaussian unit system often used in theoretical calculations, the Heaviside–Lorentz unit system, the electrostatic unit system and the electromagnetic unit system are the most important ones. Ref. 563

Keep direction under time reversal		time-even vector	

The two previous equations allow one to write the interaction between two charged bodies as

$$\frac{\mathrm{d}\boldsymbol{p}_1}{\mathrm{d}t} = \frac{1}{4\pi\varepsilon_0}\frac{q_1 q_2}{r^2}\frac{\boldsymbol{r}}{r} = -\frac{\mathrm{d}\boldsymbol{p}_2}{\mathrm{d}t}\,, \tag{429}$$

where $\mathrm{d}\boldsymbol{p}$ is the momentum change, and $\boldsymbol{r}$ is the vector connecting the two centres of mass. This famous expression for electrostatic attraction and repulsion, also due to Coulomb, is valid only for charged bodies that are of small size or spherical, and most of all, that are *at rest*.

Electric fields accelerate charges. As a result, in everyday life, electric fields have two main properties: they contain energy and they can polarize bodies. The energy content is due to the electrostatic interaction between charges. The strength of this interaction is considerable. For example, it is the basis for the force of our muscles. Muscular force is a macroscopic effect of equation 429. Another example is the material strength of steel or diamond. As we will discover, all atoms are held together by electrostatic attraction. To convince yourself of the strength of electrostatic attraction, answer the following: What is the force between two boxes with a gram of protons each, located on the two poles of the Earth? Try to guess the result before you calculate the astonishing value.

Challenge 1003 s

Coulomb's relation for the field around a charge can be rephrased in a way that helps to generalize it to non-spherical bodies. Take a closed surface, i.e., a surface than encloses a certain volume. Then the integral of the electric field over this surface, the electric flux,

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

is the enclosed charge Q divided by ε_0:

$$\oint_{\text{closed surface}} \boldsymbol{E}\, \mathrm{d}\boldsymbol{A} = \frac{Q}{\varepsilon_0}\,. \tag{430}$$

Challenge 1004 s This mathematical relation, called *Gauss's 'law'*, follows from the result of Coulomb. (In the simplified form given here, it is valid only for static situations.) Since inside conductors the electrical field is zero, Gauss's 'law' implies, for example, that if a charge q is surrounded by a uncharged metal sphere, the outer surface of the metal sphere shows Challenge 1005 e the same charge q.

Owing to the strength of electromagnetic interactions, separating charges is not an easy task. This is the reason that electrical effects have only been commonly used for about a hundred years. We had to wait for practical and efficient devices to be invented for separating charges and putting them into motion. Of course this requires energy. Batteries, as used in mobile phones, use chemical energy to do the trick.* Thermoelectric elements, as used in some watches, use the temperature difference between the wrist and the air to separate charges; solar cells use light, and dynamos or Kelvin generators use kinetic energy.

Do uncharged bodies attract one other? In first approximation they do not. But when the question is investigated more precisely, one finds that they can attract one other. Can Challenge 1007 s you find the conditions for this to happen? In fact, the conditions are quite important, as our own bodies, which are made of neutral molecules, are held together in this way.

What then is electricity? The answer is simple: *electricity is nothing in particular*. It is the name for a field of inquiry, but not the name for any specific observation or effect. Electricity is neither electric current, nor electric charge, nor electric field. Electricity is not a specific term; it applies to *all* of these phenomena. In fact the vocabulary issue hides a deeper question that remains unanswered at the beginning of the twenty-first century: what is the nature of electric charge? In order to reach this issue, we start with the following question.

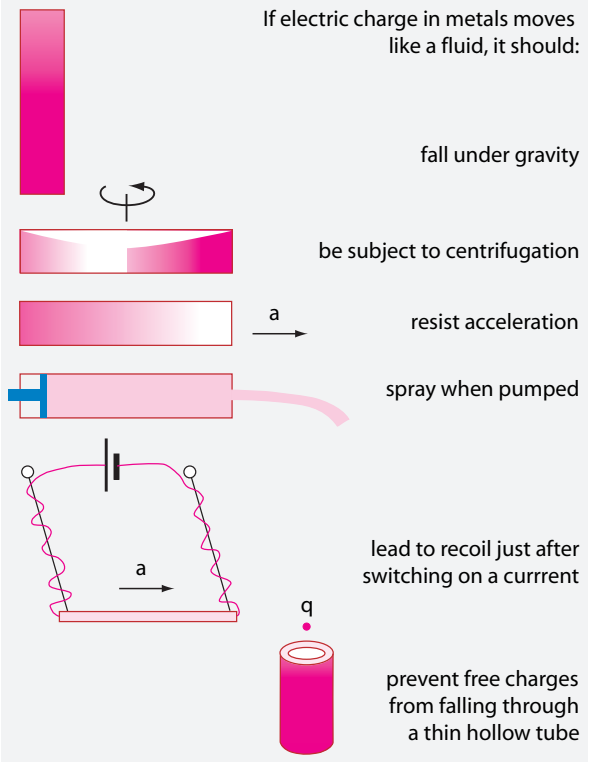
Can we detect the inertia of electricity?

If electric charge really is something *flowing* through metals, we should be able to observe the effects shown in Figure 325. Maxwell has predicted most of these effects: electric charge should fall, have inertia and be separable from matter. Indeed, each of these effects has been observed.** For example, when a long metal rod is kept vertically, we can measure an electrical potential difference, a voltage, between the top and the bottom. In other words, we can measure the *weight* of electricity in this way. Similarly, we can Ref. 564 measure the potential difference between the ends of an accelerated rod. Alternatively, we can measure the potential difference between the centre and the rim of a rotating metal disc. The last experiment was, in fact, the way in which the ratio q/m for currents

Challenge 1006 s * Incidentally, are batteries sources of charges?

** Maxwell also performed experiments to detect these effects (apart from the last one, which he did not predict), but his apparatuses were not sensitive enough.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



If electric charge in metals moves like a fluid, it should:
fall under gravity
be subject to centrifugation
a
resist acceleration
spray when pumped
a
lead to recoil just after switching on a currrent
q
prevent free charges from falling through a thin hollow tube

FIGURE 325 Consequences of the flow of electricity

in metals was first measured with precision. The result is

$$q/m = 1.8 \cdot 10^{11}\,\mathrm{C/kg} \tag{431}$$

for all metals, with small variations in the second digit. In short, electrical current has mass. Therefore, whenever we switch on an electrical current, we get a *recoil*. This simple effect can easily be measured and confirms the mass to charge ratio just given. Also, the emission of current into air or into vacuum is observed; in fact, every television tube uses this principle to generate the beam producing the picture. It works best for metal objects with sharp, pointed tips. The rays created this way – we could say that they are 'free' electricity – are called *cathode rays*. Within a few per cent, they show the same mass to charge ratio as expression (431). This correspondence thus shows that charges move almost as freely in metals as in air; this is the reason metals are such good conductors.

Ref. 565

Ref. 566

If electric charge *falls* inside vertical metal rods, we can make the astonishing deduction that cathode rays – as we will see later, they consist of free electrons* – should not be able to fall through a vertical metal tube. This is due to exact compensation of the

* The name 'electron' is due to George Stoney. Electrons are the smallest and lightest charges moving in metals; they are, usually – but not always – the 'atoms' of electricity – for example in metals. Their charge is small, 0.16 aC, so that flows of charge typical of everyday life consist of large numbers of electrons; as a result, electrical charge behaves like a continuous fluid. The particle itself was discovered and presented in

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

TABLE 63 Some observed electric current values

OBSERVATION	CURRENT
Smallest current ever measured (for one moving electron)	3 aA
Human nerve signals	20 μA
Lethal current for humans	as low as 20 mA, typically 100 mA
Current drawn by a train engine	600 A
Current in a lightning bolt	10 to 100 kA
Highest current produced by humans	20 MA
Current inside the Earth	around 100 MA

acceleration by the electrical field generated by the displaced electricity in the tube and the acceleration of gravity. Thus electrons should not be able to fall through a long thin cylinder. This would not be the case if electricity in metals did not behave like a fluid. The experiment has indeed been performed, and a reduction of the acceleration of free fall for electrons of 90 % has been observed. Can you imagine why the ideal value of 100 % is not achieved?

Challenge 1008 e

Ref. 567

Challenge 1009 s

If electric current behaves like a liquid, one should be able to measure its speed. The first to do so, in 1834, was Charles Wheatstone. In a famous experiment, he used a wire of a quarter of a mile length, to produce three sparks: one at the start, one at the middle, and one at the end. He then mounted a rapidly moving mirror on a mechanical watch; by noting how much the three spark images were shifted against each other on a screen, he determined the speed to be 0.45 Gm/s, though with a large error. Latter, more precise measurements showed that the speed is always below 0.3 Gm/s, and that it depends on the metal and the type of insulation of the wire. The high value of the speed convinced many people to use electricity for transmitting messages. A modern version of the experiment, for computer fans, uses the 'ping' command from the UNIX operating system. The 'ping' command measures the time for a computer signal to reach another computer and return back. If the cable length between two computers is known, the signal speed can be deduced. Just try.

Ref. 568

Challenge 1010 e

As a note, the speed of electricity is too slow for many people. Modern computers that are connected to stock exchanges are located as near as possible to the stock exchange, because the time advantage the short communication distance provides is essential for getting a good financial performance in certain trading markets.

Ref. 569

In summary, experiments show that all charges have mass. And like all massive bodies they move slower than light.

FEELING ELECTRIC FIELDS

Why is electricity dangerous to humans? The main reason is that the human body is controlled by 'electric wires' itself. As a result, outside electricity interferes with the internal

1897 by the Prussian physicist Johann Emil Wiechert (1861–1928) and, independently, three months later, by the British physicist Joseph John Thomson (1856–1940).

signals. This has been known since 1789. In that year the Italian medical doctor Luigi Galvani (1737–1798) discovered that electrical current makes the muscles of a dead animal contract. The famous first experiment used frog legs: when electricity was applied to them, they twitched violently. Subsequent investigations confirmed that all nerves make use of electrical signals. Nerves are the 'control wires' of animals. However, nerves are not made of metal: metals are not sufficiently flexible. As a result, nerves do not conduct electricity using electrons but by using *ions*. The finer details were clarified only in the twentieth century. Nerve signals propagate using the motion of sodium and potassium ions in the cell membrane of the nerve. The resulting signal speed is between 0.5 m/s and 120 m/s, depending on the type of nerve. This speed is sufficient for the survival of most species – it signals the body to run away in case of danger.

Being electrically controlled, all mammals can sense strong electric fields. Humans can sense fields down to around 10 kV/m, when hair stands on end. In contrast, several animals can sense weak electric and magnetic fields. Sharks, for example, can detect fields down to 1 μV/m using special sensors, the *Ampullae of Lorenzini*, which are found around their mouth. Sharks use them to detect the field created by prey moving in water; this allows them to catch their prey even in the dark. Several freshwater fish are also able to detect electric fields. The salamander and the platypus, the famous duck-billed mammal, can also sense electric fields. Like sharks, they use them to detect prey in water which is too muddy to see through. Certain fish, the so-called *weakly-electric fish*, even generate a weak field in order to achieve better prey detection.*

No land animal has special sensors for electric fields, because any electric field in air is strongly damped when it encounters a water-filled animal body. Indeed, the usual atmosphere has an electric field of around 100 V/m; inside the human body this field is damped to the μV/m range, which is much less than an animal's internal electric fields. In other words, humans do not have sensors for low electric fields because they are land animals. (Do humans have the ability to sense electric fields in water? Nobody seems to know.) However, there a few exceptions. You might know that some older people can sense approaching thunderstorms in their joints. This is due the coincidence between the electromagnetic field frequency emitted by thunderclouds – around 100 kHz – and the resonant frequency of nerve cell membranes.

Challenge 1011 r

Page 732

The water content of the human body also means that the electric fields in air that are

* It took until the year 2000 for technology to make use of the same effect. Nowadays, airbag sensors in cars often use electric fields to sense whether the person sitting in the seat is a child or an adult, thus changing the way that the bag behaves in an accident.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

found in nature are rarely dangerous to humans. Whenever humans do sense electric fields, such as when high voltage makes their hair stand on end, the situation is potentially dangerous.

The high impedance of air also means that, in the case of time-varying electromagnetic fields, humans are much more prone to be affected by the magnetic component than by the electric component.

Magnets

The study of magnetism progressed across the world independently of the study of electricity. Towards the end of the twelfth century, the compass came into use in Europe. At that time, there were heated debates on whether it pointed to the north or the south. In 1269, the French military engineer Pierre de Maricourt (1219–1292) published his study
Ref. 570 of magnetic materials. He found that every magnet has *two* points of highest magnetization, and he called them *poles*. He found that even after a magnet is cut, the resulting pieces always retain two poles: one points to the north and the other to the south when the stone is left free to rotate. Magnets are dipoles. Atoms are either dipoles or unmagnetic. There are no magnetic monopoles. Despite the promise of eternal fame, no magnetic monopole has ever been found, as shown in Table 57. Like poles repel, and unlike poles attract.

Magnets have a second property: magnets transform unmagnetic materials into magnetic ones. There is thus also a magnetic polarization, similar to the electric polarization. Unlike the electric case, some magnetic materials retain the induced magnetic polarization: they become magnetized. This happens when the atoms in the material get aligned by the external magnet.

Can humans feel magnetic fields?

> Any fool can ask more questions than seven sages can answer.
>
> Antiquity

It is known that honey bees, sharks, pigeons, salmon, trout, sea turtles and certain bacte-
Ref. 571 ria can feel magnetic fields. One speaks of the ability for magnetoreception. All these life forms use this ability for navigation. The most common detection method is the use of small magnetic particles inside a cell; the cell then senses how these small built-in magnets move in a magnetic field. The magnets are tiny, typically around 50 nm in size. These small magnets are used to navigate along the magnetic field of the Earth. For higher animals, the variations of the magnetic field of the Earth, 20 to 70 μT, produce a landscape that is similar to the visible landscape for humans. They can remember it and use it for navigation.

Can humans feel magnetic fields? Magnetic material seems to be present in the human brain, but whether humans can feel magnetic fields is still an open issue. Maybe you can
Challenge 1012 r devise a way to check this?

Are magnetism and electricity related? François Arago* found out that they were. He observed that a ship that had survived a bad thunderstorm and had been struck by light-

* François Arago (1786–1853) French physicist.

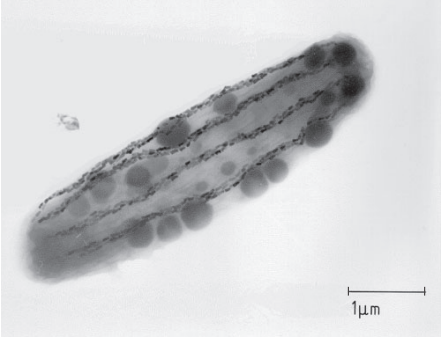

FIGURE 326 The magnetotactic bacterium *Magnetobacterium bavaricum* with its magnetosomes (© Marianne Hanzlik)

ning, needed a new compass. Thus lightning has the ability to demagnetize compasses. Arago knew, like Franklin, that lightning is an electrical phenomena. In other words, electricity and magnetism must be related. More precisely, magnetism must be related to the *motion* of electricity.

How can one make a motor?

> Communism is the power of the local councils plus electricification of the whole country.
> Lenin.*

The reason for Lenin's famous statement were two discoveries. One was made in 1820 by the Danish physicist Hans Christian Oersted (1777–1851) and the other in 1831 by the English physicist Michael Faraday.** The consequences of these experiments changed the world completely in less than one century.

On the 21st of July of 1821, Oersted published a leaflet, in Latin, which took Europe by storm. Oersted had found (during a lecture demonstration to his students) that when a current is sent through a wire, a nearby magnet is put into motion. In other words, he found that the flow of electricity can move bodies.

Further experiments show that *two* wires in which charges flow attract or repel each other, depending on whether the currents are parallel or antiparallel. These and other experiments show that wires in which electricity flows behave like magnets.*** In other

* Lenin (b. 1870 Simbirsk, d. 1924 Gorki), founder of the Union of Soviet Socialist Republics, in 1920 stated this as the centre of his development plan for the country. In Russian, the local councils of that time were called soviets.

** Michael Faraday (b. 1791 Newington Butts, d. 1867 London) was born to a simple family, without schooling, and of deep and naive religious ideas. As a boy he became assistant to the most famous chemist of his time, Humphry Davy (1778–1829). He had no mathematical training, but late in his life he became member of the Royal Society. A modest man, he refused all other honours in his life. He worked on chemical topics, the atomic structure of matter and, most of all, he developed the idea of (magnetic) fields and field lines. He used fields to describe all his numerous experimental discoveries about electromagnetism, such as the Faraday effect. Fields were later described mathematically by Maxwell, who at that time was the only person in Europe to take over Faraday's field concept.

*** In fact, if one imagines tiny currents moving in circles inside magnets, one gets a unique description for all magnetic fields observed in nature.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

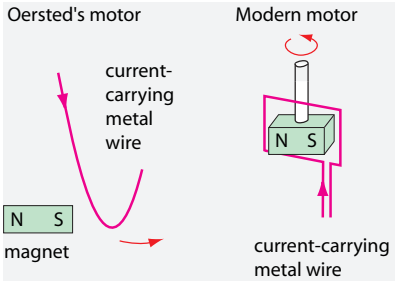

FIGURE 327 An old and a newer version of an electric motor

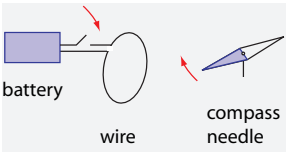

FIGURE 328 An electrical current always produces a magnetic field

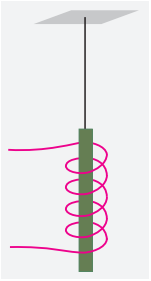

FIGURE 329 Current makes a metal rod rotate

words, Oersted had found the definite proof that electricity could be turned into magnetism.

Shortly afterwards, Ampère* found that *coils* increase these effects dramatically. Coils behave like small magnets. In particular, coils, like magnetic fields, always have two poles, usually called the north and the south pole. Opposite poles attract, like poles repel each other. As is well known, the Earth is itself a large magnet, with its magnetic north pole near the geographic south pole, and vice versa. (The magnetic field of the Earth is *not* due to a solid permanent magnet inside it. The Earth's solid core is too hot to be a permanent magnet; instead, the magnetic field is due to circulating currents in the outer, liquid core.)

Moving electric charge produces magnetic fields. This result explains why magnetic fields always have two poles. The lack of magnetic monopoles thus becomes clear. But one topic is strange. If magnetic fields are due to the motion of charges, this must be also the case for a normal magnet. Can this be shown?

In 1915, two men in the Netherlands found a simple way to prove that even in a magnet,

* André-Marie Ampère (b. 1775 Lyon, d. 1836 Marseille), French physicist and mathematician. Autodidact, he read the famous *Encyclopédie* as a child; in a life full of personal tragedies, he wandered from maths to chemistry and physics, worked as a school teacher, and published nothing of importance until 1820. Then the discovery of Oersted reached all over Europe: electrical current can deviate magnetic needles. Ampère worked for years on the problem, and in 1826 published the summary of his findings, which lead Maxwell to call him the 'Newton of electricity'. Ampère named and developed many areas of electrodynamics. In 1832, he and his technician also built the first dynamo, or rotative current generator. Of course, the unit of electrical current is named after him.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

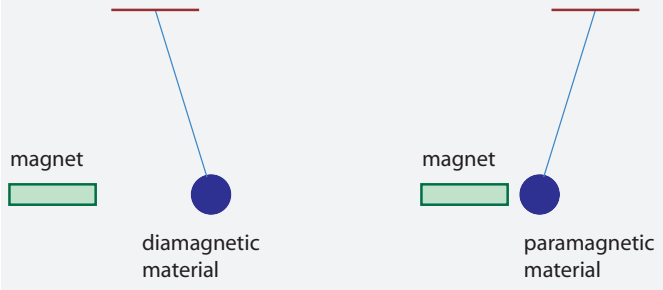

FIGURE 330 The two basic types of magnetic material behaviour (tested in an inhomogeneous field): diamagnetism and paramagnetism

something is moving. They suspended a metal rod from the ceiling by a thin thread and then put a coil around the rod, as shown in Figure 329. They predicted that the tiny currents inside the rod would become aligned by the magnetic field of the coil. As a result, they expected that a current passing through the coil would make the rod turn around its axis. Indeed, when they sent a strong current through the coil, the rod rotated. (As a result of the current, the rod was magnetized.) Today, this effect is called the *Einstein–de Haas effect* after the two physicists who imagined, measured and explained it.* The effect thus shows that even in the case of a permanent magnet, the magnetic field is due to the internal motion of charges. The size of the effect also shows that the moving particles are electrons. (Twelve years later it became clear that the angular momentum of the electrons responsible for the effect is a mixture of orbital and spin angular momentum; in fact, the electron spin plays a central role in the effect.)

Ref. 572

Since magnetism is due to the alignment of microscopic rotational motions, an even more surprising effect can be predicted. Simply rotating a ferromagnetic material** should magnetize it, because the tiny rotating currents would then be aligned along the axis of rotation. This effect has indeed been observed; it is called the *Barnett effect* after its discoverer. Like the Einstein–de Haas effect, the Barnett effect can also be used to determine the gyromagnetic ratio of the electron; thus it also proves that the spins of electrons (usually) play a larger role in magnetism than their orbital angular momentum.

Ref. 573

Page 1037

Magnetic fields

Experiments show that the magnetic field always has a given direction in space, and a magnitude common to all (resting) observers, whatever their orientation. We are tempted to describe the magnetic field by a vector. However, this would be wrong, since a magnetic field does not behave like an arrow when placed before a mirror. Imagine that a system produces a magnetic field directed to the right. You can take any system, a coil, a machine, etc. Now build or imagine a second system that is the exact mirror version of the first: a mirror coil, a mirror machine, etc. The magnetic system produced by the

* Wander Johannes de Haas (1878–1960), Dutch physicist. De Haas is best known for two additional magneto-electric effects named after him, the Shubnikov–de Haas effect (the strong increase of the magnetic resistance of bismuth at low temperatures and high magnetic fields) and the de Haas–Van Alphen effect (the diamagnetic susceptibility of bismuth at low temperatures is a periodic function of the magnetic field).

** A ferromagnetic material is a special kind of paramagnetic material that has a permanent magnetization.

mirror system does not point to the left, as maybe you expected: it still points to the right. (Check by yourself.) In simple words, magnetic fields do *not* fully behave like arrows.

Challenge 1013 e

In other words, it is not completely correct to describe a magnetic field by a vector $\boldsymbol{B} = (B_x, B_y, B_z)$, as vectors behave like arrows. One also speaks of a *pseudovector*; angular momentum and torque are also examples of such quantities. The precise way is to describe the magnetic field by the quantity*

$$\boldsymbol{B} = \begin{pmatrix} 0 & -B_z & B_y \\ B_z & 0 & -B_x \\ -B_y & B_x & 0 \end{pmatrix}, \tag{432}$$

called an *antisymmetric tensor*. In summary, *magnetic fields* are defined by the accelera-

* The quantity $\boldsymbol{B}$ was not called the 'magnetic field' until recently. We follow here the modern, logical definition, which supersedes the traditional one, where $\boldsymbol{B}$ was called the 'magnetic flux density' or 'magnetic induction' and another quantity, $\boldsymbol{H}$, was called – incorrectly, but for over a century – the magnetic field. This quantity $\boldsymbol{H}$ will not appear in this walk, but it is important for the description of magnetism in materials.

tion they impart on moving charges. This acceleration turns out to follow

$$\boldsymbol{a} = \frac{e}{m}\boldsymbol{v}\boldsymbol{B} = \frac{e}{m}\boldsymbol{v} \times \boldsymbol{b} \tag{433}$$

a relation which is often called *Lorentz acceleration*, after the important Dutch physicist Hendrik A. Lorentz (b. 1853 Arnhem, d. 1928 Haarlem) who first stated it clearly.* (The relation is also called the *Laplace acceleration*.) The unit of the magnetic field is called tesla and is abbreviated T. One has $1\,\mathrm{T} = 1\,\mathrm{N\,s/C\,m} = 1\,\mathrm{V\,s/m^2} = 1\,\mathrm{V\,s^2/A\,m}$.

The Lorentz acceleration is the effect at the root of any electric motor. An electric motor is a device that uses a magnetic field as efficiently as possible to accelerate charges

Challenge 1014 s

* Does the definition of magnetic field given here assume a charge speed much lower than that of light?

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

flowing in a wire. Through the motion of the charges, the wire is then also moved. Electricity is thus transformed into magnetism and then into motion. The first efficient motor was built back in 1834.

As in the electric case, we need to know how the *strength* of a magnetic field is determined. Experiments such as Oersted's show that the magnetic field is due to moving charges, and that a charge moving with velocity $\boldsymbol{v}$ produces a field $\boldsymbol{B}$ given by

$$\boldsymbol{B}(\boldsymbol{r}) = \frac{\mu_0}{4\pi}\, q\, \frac{\boldsymbol{v}\times\boldsymbol{r}}{r^3} \quad \text{where} \quad \frac{\mu_0}{4\pi} = 10^{-7}\,\mathrm{N/A^2}\,. \tag{434}$$

This is called *Ampère's 'law'*. Again, the strange factor $\mu_0/4\pi$ is due to the historical way in which the electrical units were defined. The constant μ_0 is called the *permeability of the vacuum* and is defined by the fraction of newtons per ampere squared given in the formula. It is easy to see that the magnetic field has an intensity given by $\boldsymbol{v}E/c^2$, where
Challenge 1015 e $\boldsymbol{E}$ is the electric field measured by an observer moving *with* the charge. This is the first hint that magnetism is a relativistic effect.

We note that equation (434) is valid only for small velocities and accelerations. Can
Challenge 1016 s you find the general one?

In 1831, Michael Faraday discovered an additional piece of the puzzle, one that even the great Ampère had overlooked. He found that a *moving* magnet could cause a current flow in an electrical circuit. Magnetism can thus be turned into electricity. This important discovery allowed the production of electrical current flow by generators, so-called *dynamos*, using water power, wind power or steam power. In fact, the first dynamo was built in 1832 by Ampère and his technician. Dynamos started the use of electricity throughout the world. Behind every electrical wall plug there is a dynamo somewhere.

Additional experiments show that magnetic fields also lead to electric fields when one changes to a moving viewpoint. You might check this on any of the examples of Figures 327 to 345. *Magnetism indeed is relativistic electricity*. Electric and magnetic fields are partly transformed into each other when switching from one inertial reference frame to the other. Magnetic and electrical fields thus behave like space and time, which are also mixed up when changing from one inertial frame to the other. The theory of special relativity thus tells us that there must be a single concept, an *electromagnetic field*, describing them both. Investigating the details, one finds that the electromagnetic field $\boldsymbol{F}$ surrounding charged bodies has to be described by an antisymmetric 4-*tensor*

$$\boldsymbol{F}^{\mu\nu} = \begin{pmatrix} 0 & -E_x/c & -E_y/c & -E_z/c \\ E_x/c & 0 & -B_z & B_y \\ E_y/c & B_z & 0 & -B_x \\ E_z/c & -B_y & B_x & 0 \end{pmatrix} \text{ or } \boldsymbol{F}_{\mu\nu} = \begin{pmatrix} 0 & E_x/c & E_y/c & E_z/c \\ -E_x/c & 0 & -B_z & B_y \\ -E_y/c & B_z & 0 & -B_x \\ -E_z/c & -B_y & B_x & 0 \end{pmatrix}. \tag{435}$$

Obviously, the electromagnetic field F, and thus every component of these matrices, depends on space and time. The matrices show that electricity and magnetism are two faces of the same effect.* In addition, since electric fields appear only in the topmost row and

* Actually, the expression for the field contains everywhere the expression $1/\sqrt{\mu_0\varepsilon_0}$ instead of the speed of light c. We will explain the reason for this substitution shortly.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

leftmost column, the expressions show that in everyday life, for small speeds, electricity and magnetism *can* be separated. (Why?) Challenge 1017 s

The total influence of electric and magnetic fields on fixed or moving charges is then given by the following expression for the relativistic force-acceleration relation $\boldsymbol{K} = m\boldsymbol{b}$:

$$
\begin{aligned}
& m\boldsymbol{b} = q\boldsymbol{F}u \quad \text{or} \\
& mb^{\mu} = m\,\frac{\mathrm{d}u^{\mu}}{\mathrm{d}\tau} = q\boldsymbol{F}^{\mu}{}_{\nu}u^{\nu} \quad \text{or} \\
& m\frac{\mathrm{d}}{\mathrm{d}\tau}\begin{pmatrix} \gamma c \\ \gamma v_x \\ \gamma v_y \\ \gamma v_z \end{pmatrix} = q\begin{pmatrix} 0 & E_x/c & E_y/c & E_z/c \\ E_x/c & 0 & B_z & -B_y \\ E_y/c & -B_z & 0 & B_x \\ E_z/c & B_y & -B_x & 0 \end{pmatrix}\begin{pmatrix} \gamma c \\ \gamma v_x \\ \gamma v_y \\ \gamma v_z \end{pmatrix} \quad \text{or} \\
& W = q\boldsymbol{E}\boldsymbol{v} \quad \text{and} \quad d\boldsymbol{p}/\mathrm{d}t = q(\boldsymbol{E} + \boldsymbol{v} \times \boldsymbol{B})\,,
\end{aligned}
\tag{436}
$$

which show how the work W and the three-force $dp/\mathrm{d}t$ depend on the electric and magnetic fields. All four expressions describe the same content; the simplicity of the first one is the reason for the involved matrices (435) of the electromagnetic field. In fact, the extended *Lorentz relation* (436) is the *definition* of the electromagnetic field, since the field is defined as that 'stuff' which accelerates charges. In particular, all devices that put charges into motion, such as batteries and dynamos, as well as all devices that are put into motion by flowing charges, such as electric motors and muscles, are described by this relation. That is why this relation is usually studied, in simple form, already in school. The Lorentz relation describes all cases in which the motion of objects can be seen by the naked eye or felt by our senses, such as the movement of an electrical motor in a high speed train, in a lift and in a dental drill, the motion of the picture generating electron beam in a television tube, or the travelling of an electrical signal in a cable and in the nerves of the body. Ref. 574, Ref. 575

In summary, we found that the interaction between charges can be described in two statements: First, charges are affected by electric and magnetic fields; second, charges produce electric and magnetic fields.

Electromagnetic fields and Lagrangians

In the expression for the Lorentz acceleration (436) it is understood that one sums over indices that appear twice. The electromagnetic field tensor $\boldsymbol{F}$ is an *antisymmetric* 4-tensor. (Can you write down the relation between $\boldsymbol{F}^{\mu\nu}$, $\boldsymbol{F}_{\mu\nu}$ and $\boldsymbol{F}^{\mu}{}_{\nu}$?) Like any antisymmetric tensor, the electromagnetic field has two invariants, i.e., two deduced properties that are the same for every observer: the expression $B^2 - E^2/c^2 = \frac{1}{2}\mathrm{tr}\,\boldsymbol{F}^2$ and the product $4\boldsymbol{E}\boldsymbol{b} = -c\,\mathrm{tr}\,\boldsymbol{F}^*\boldsymbol{F}$. (Can you confirm this, using the definition of trace as the sum of the diagonal elements?) Challenge 1018 ny Challenge 1019 s

The first invariant expression, $B^2 - E^2/c^2 = \frac{1}{2}\mathrm{tr}\,\boldsymbol{F}^2$, turns out to be (proportional to) the Lagrangian of the electromagnetic field. It is a scalar. The first invariant implies that if E is larger, smaller or equal to cB for one observer, it also is for all other observers. The Lagrangian can be used to define the action, which can be used to describe the motion of the electromagnetic field using the principle of least action. You can check yourself that the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Challenge 1020 e Lagrangian indeed allows describing the change due to evolving electromagnetic fields. This approach is another way to deduce Maxwell's field equations of electromagnetism.

The second invariant of the electromagnetic field tensor, $4\boldsymbol{EB} = -c \operatorname{tr} \boldsymbol{F}^* \boldsymbol{F}$, is a pseudoscalar; it describes whether the angle between the electric and the magnetic field is acute or obtuse for all observers.*

The application of electromagnetic effects to daily life has changed the world. For example, the installation of electric lighting in city streets has almost eliminated the previously so common night assaults. These and all other electrical devices exploit the fact that charges can flow in metals and, in particular, that electromagnetic energy can be transformed

— into mechanical energy – as used in loudspeakers, motors, piezo crystals;
— into light – as in lamps and lasers;
— into heat – as in electric ovens, blankets and tea pots;
— into chemical effects – as in hydrolysis, battery charging and electroplating;
— into coldness – as in refrigerators and Peltier elements;
— into radiation signals – as in radio and television;
— into stored information – as in magnetic records and in computers.

Electrical light, lasers, batteries, electric motors, radio, telephone, X-rays, television and computers have changed human life completely in less than one century.

How motors prove relativity to be right

> The only mathematical operation I performed in my life was to turn the handle of a calculator.
> Michael Faraday

All electric motors are based on the result that electric currents interact with magnetic fields. The simplest example is the attraction of two wires carrying parallel currents. This observation alone, made in 1820 by Ampère, is sufficient to make motion larger than a Ref. 577 certain maximal speed impossible.

The argument is beautifully simple. We change the original experiment and imagine two long, electrically charged rods of mass m, moving in the same direction with velocity v and separation d. An observer moving with the rods would see an electrostatic Challenge 1022 e repulsion between the rods given by

* There is in fact a third Lorentz invariant, much less known. It is specific to the electromagnetic field and is a combination of the field and its vector potential:

$$\begin{aligned}\kappa_3 &= \frac{1}{2} A_\mu A^\mu \boldsymbol{F}_{\rho\nu} \boldsymbol{F}^{\nu\rho} - 2A_\rho \boldsymbol{F}^{\rho\nu} \boldsymbol{F}_{\nu\mu} A^\mu \\ &= (\boldsymbol{AE})^2 + (\boldsymbol{Ab})^2 - |\boldsymbol{A} \times \boldsymbol{E}|^2 - |\boldsymbol{A} \times \boldsymbol{B}|^2 + 4\frac{\varphi}{c}(\boldsymbol{AE} \times \boldsymbol{B}) - (\frac{\varphi}{c})^2 (E^2 + B^2) \,. \end{aligned} \tag{437}$$

Ref. 576 This expression is Lorentz (but not gauge) invariant; knowing it can help clarify unclear issues, such as the lack of existence of waves in which the electric and magnetic fields are parallel. Indeed, for plane monochromatic waves all three invariants *vanish* in the Lorentz gauge. Also the quantities $\partial_\mu J^\mu$, $J_\mu A^\mu$ and $\partial_\mu A^\mu$ are Challenge 1021 s Lorentz invariants. (Why?) The latter, the frame independence of the divergence of the four-potential, reflects the invariance of gauge choice. The gauge in which the expression is set to zero is called the *Lorentz gauge*.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

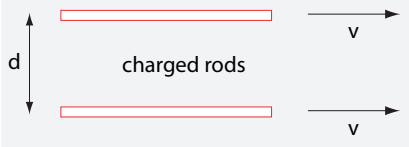

FIGURE 331 The relativistic aspect of magnetism

$$ma_e = -\frac{1}{4\pi\varepsilon_0}\frac{2\lambda^2}{d} \tag{438}$$

where λ is the charge per length of the rods. A second, *resting* observer sees two effects: the electrostatic repulsion and the attraction discovered by Ampère. The second observer therefore observes

Challenge 1023 e

$$ma_{em} = -\frac{1}{4\pi\varepsilon_0}\frac{2\lambda^2}{d} + \frac{\mu_0}{2\pi}\frac{\lambda^2 v^2}{d} \,. \tag{439}$$

This expression must be consistent with the observation of the first observer. This is the case only if both observers find repulsions. It is easy to check that the second observer sees a repulsion, as does the first one, only if

$$v^2 < \frac{1}{\varepsilon_0\mu_0} \,. \tag{440}$$

This maximum speed, with a value of 0.3 GM/s, is thus valid for any object carrying charges. But *all* everyday objects contain charges: there is thus a maximum speed for matter.

Challenge 1024 d

Are you able to extend the argument for a maximum speed to neutral particles as well? We will find out more on this limit velocity, which we know already, in a minute.

Another argument for magnetism as a relativistic effect is the following. In a wire with electrical current, the charge is zero for an observer at rest with respect to the wire. The reason is that the charges enter and exit the wire at the same time for that observer. Now imagine an observer who flies along the wire. The entrance and exit events do not occur simultaneously any more; the wire is charged for a moving observer. (The charge depends on the direction of the observer's motion.) In other words, if the observer himself were charged, he would experience a force. Moving charges experience forces from current-carrying wires. This is exactly why magnetic fields were introduced: they only produce forces on *moving* charges. In short, current carrying wires are surrounded by magnetic fields.

In summary, electric effects are due to flow of electric charges and to electric fields; magnetism is due to *moving* electric charges. It is *not* due to magnetic charges.* The strength of magnetism, used in any running electric motor, proves relativity right: there is a maximum speed in nature for all masses and charges. Both electric and magnetic fields carry energy and momentum. They are two faces of the same coin.

Page 773
Challenge 1025 d

* 'Electrons move in metal with a speed of about 1 μm/s; thus if I walk with the same speed along a cable carrying a constant current, I should not be able to sense any magnetic field.' What is wrong with this argument?

TABLE 68 Voltage values observed in nature

Observation	Voltage
Smallest measured voltage	*c.* 10 fV
Human nerves	70 mV
Volta cell	1 V
Voltaic cell ('battery')	1.5 V
Mains in households	230 V or 110 V
Electric eel	100 to 600 V
Tramway supply	500 V
Sparks when rubbing a polymer pullover	1 kV
Electric fence	0.7 to 10 kV
Train supply	15 kV
Ignition plug in cars	15 kV
Colour television tube	30 kV
X-ray tube	30 to 200 kV
Electron microscopes	0.5 kV to 3 MV
Stun gun	65 to 600 kV
Lightning stroke	10 to 100 MV
Record accelerator voltage	1 TV
Planck voltage, highest value possible in nature	$1.0 \cdot 10^{27}$ V

Curiosities and fun challenges about things electric and magnetic

> Et facta mirari et intellectua assequi.
> Augustine of Hippo

Before we study the motion of an electromagnetic field in detail, let's have some fun with electricity.

* *

Nowadays, having fun with sparks is straightforward. Tesla coils, named after Nikola Tesla * are the simplest devices that allow long sparks to be produced at home. Attention: this is dangerous; that is the reason that such devices cannot be bought (almost) anywhere. The basic diagram and an example is shown in Figure 332. Tesla coils look like large metal mushrooms (to avoid unwanted discharges) and plans for their construction can be found on numerous websites or from numerous enthusiast's clubs, such as www.stefan-kluge.de.

* Никола Тесла (1856 Smiljan–1943 New York City), Serbian engineer and inventor. He invented and promoted the polyphase alternating current system, the alternating current electric motor, wireless communication, fluorescent lighting and many other applications of electricity. He is also one of the inventors of radio. The SI unit of the magnetic field is named after him. A flamboyant character, his ideas were sometimes unrealistic; for example he imagined that Tesla coils could be used for wireless power transmission.

* *

In the basement of a house there are three switches that control three light bulbs in the first floor. You are in the basement and are allowed to go to the first floor only once. How do you find out which switch controls which bulb?

Challenge 1031 e

* *

How do you wire up a light bulb to the mains and three switches so that the light can be switched on at any of the switches and off at any other switch? And for four switches? Nobody will take a physicist seriously who is able to write Maxwell's equations but cannot solve this little problem.

Challenge 1032 s

* *

The first appliances built to generate electric currents were large rubbing machines. Then, in 1799 the Italian scientist Alessandro Volta (1745–1827) invented a new device to generate electricity and called it a *pile*; today its basic element is called a *(voltaic) cell*, a *primary cell** or, less correctly, a *battery*. (Correctly speaking, a battery is a collection of cells, as the one found in a car.) Voltaic cells are based on chemical processes; they provide much more current and are smaller and easier to handle than electrostatic machines. The invention of the battery changed the investigation of electricity so profoundly that Volta became world famous. At last, a simple and reliable source of electricity was available for use in experiments; unlike rubbing machines, piles are compact, work in all weather conditions and make no noise.

An apple or a potato with a piece of copper and one of zinc inserted is one of the simplest possible voltaic cells. It provides a voltage of about 1 V and can be used to run digital clocks or to produce clicks in headphones. Volta was also the discoverer of the charge law $q = CU$ of capacitors (C being the capacity, and U the voltage) and the inven-

* A *secondary cell* is a rechargeable cell.

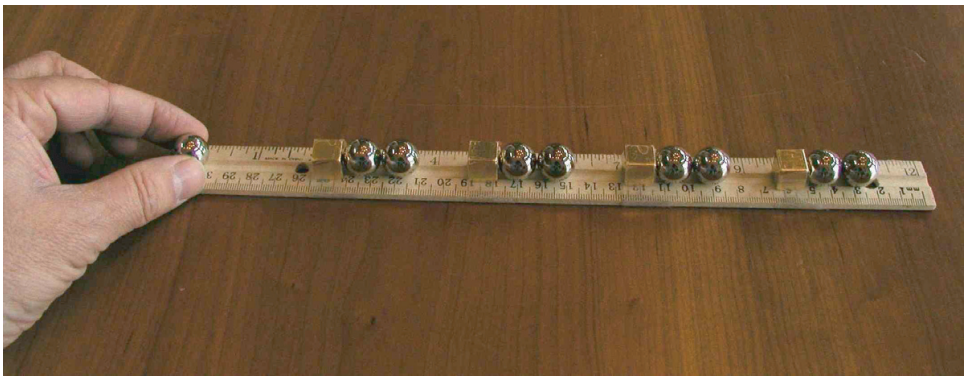

FIGURE 334 A Gauss rifle, made with a few steel balls and four magnets attached to a ruler with scotch tape (© Simon Quellen Field)

tor of the high sensitivity capacitor electroscope. A modest man, nevertheless, the unit of electrical potential, or 'tension', as Volta used to call it, was deduced from his name. A 'battery' is a large number of voltaic cells; the term was taken from an earlier, almost purely military use.* A battery in a mobile phone is just an elaborated replacement for a number of apples or potatoes.

* *

A PC or a telephone can communicate without wires, by using radio waves. Why are these and other electrical appliances not able to obtain their *power* via radio waves, thus eliminating power cables?

Challenge 1034 s

* *

Magnets can be used to accelerate steel balls. The most famous example is the *Gauss rifle* shown in Figure 334. If the leftmost ball is gently rolled towards the first magnet, the third ball is strongly kicked away. Then the process repeats: the speed increases even more for the fifth, the seventh and the ninth ball. The experiment never fails to surprise whoever seees it for the first time. Where does the momentum of the final ball come from?

Challenge 1035 e

* *

Objects that are not right–left symmetric are called *chiral*, from the Greek word for 'hand'. Can you make a mirror that does not switch chirality (i.e., does not 'switch left and right')? In two different ways?

Challenge 1036 s

* *

A Scotch tape roll is a dangerous device. Pulling the roll quickly leads to light emission (through triboluminescence) and to small sparks. It is suspected that several explosions in mines were triggered when such a spark ignited a combustible gas mixture.

* A pile made of sets of a zinc plate, a sheet of blotting paper soaked with salt water and a copper coin is easily constructed at home and tested with a calculator or a digital watch.

Challenge 1033 e

* *

Take an envelope, wet it and seal it. After letting it dry for a day or more, open it in the dark. At the place where the two sides of paper are being separated from each other, the envelope glows with a blue colour. Why? Is it possible to speed up the test using a hair dryer?

Challenge 1037 s

* *

Electromagnetism is full of surprises and offers many effects that can be reproduced at home. The internet is full of descriptions of how to construct Tesla coils to produce sparks, coil guns or rail guns to shoot objects, electrostatic machines to make your hair stand on end, glass spheres with touch-sensitive discharges and much more. If you like experiments, just search for these terms.

* *

A high voltage can lead to current flow through air, because air becomes conductive in high electric fields. In such discharges, air molecules are put in motion. As a result, one can make objects that are attached to a pulsed high tension source lift up in the air, if one optimizes this air motion so that it points downwards everywhere. The high tension is thus effectively used to accelerate ionized air in one direction and, as a result, an object will move in the opposite direction, using the same principle as a rocket. An example is shown in Figure 335, using the power supply of a PC monitor. (Watch out: danger!) Numerous websites explain how to build these so-called lifters at home; in Figure 335, the bottle and the candle are used as high voltage insulator to keep one of the two thin high voltage wires (not visible in the photograph) high enough in the air, in order to avoid discharges to the environment or to interfere with the lifter's motion. Unfortunately, the majority of websites – not all – give incorrect or confused explanations of the phenomenon. These websites thus provide a good challenge for one to learn to distinguish fact from speculation.

Challenge 1038 e

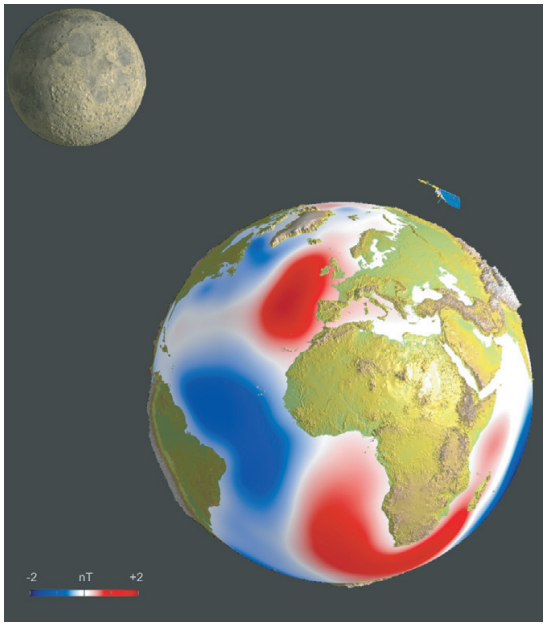

FIGURE 336 The magnetic field due to the tides (© Stefan Maus)

* *

The electric effects produced by friction and by liquid flow are usually small. However, in the 1990s, a number oil tankers disappeared suddenly. The sailors had washed out the oil tanks by hosing sea water onto the tank walls. The spraying led to charging of the tank; a discharge then led to the oil fumes in the tank igniting. This led to an explosion and subsequently the tankers sank. Similar accidents also happen regularly when chemicals are moved from one tank to another.

* *

Rubbing a plastic spoon with a piece of wool charges it. Such a charged spoon can be used to extract pepper from a salt–pepper mixture by holding the spoon over the mixture. Why?

Challenge 1039 s

* *

When charges move, they produce a magnetic field. In particular, when ions inside the Earth move due to heat convection, they produce the Earth's magnetic field. When the ions high up in the atmosphere are moved by solar wind, a geomagnetic storm appears; its field strength can be as high as that of the Earth itself. In 2003, an additional mechanism was discovered. When the tides move the water of the oceans, the ions in the salt water produce a tiny magnetic field; it can be measured by highly sensitive magnetometers in satellites orbiting the Earth. After two years of measurements from a small satellite it was possible to make a beautiful film of the oceanic flows. Figure 336 gives an impression.

* *

The names electrode, electrolyte, ion, anode and cathode were suggested by William Whewell (1794–1866) on demand of Michael Faraday; Faraday had no formal education and asked his friend Whewell to form two Greek words for him. For anode and cathode, Whewell took words that literally mean 'upward street' and 'downward street'. Faraday then popularized these terms, like the other words mentioned above.

* *

Challenge 1040 s The shortest light pulse produced so far had a length of 100 as. To how many wavelengths of green light would that correspond?

* *

Challenge 1041 s Why do we often see shadows of houses and shadows of trees, but never shadows of the electrical cables hanging over streets?

* *

Challenge 1042 s How would you measure the speed of the tip of a lightning bolt? What range of values do you expect?

* *

Ref. 581 One of the simplest possible electric motors was discovered by Faraday in 1831. A magnet suspended in mercury will start to turn around its axis if a current flows through it. (See Figure 337.) In addition, when the magnet is forced to turn, the device (often also called Barlow's wheel) also works as a current generator; people have even tried to generate Challenge 1043 s domestic current with such a system! Can you explain how it works?

The modern version of this motor makes use of a battery, a wire, a conductive samarium–cobalt magnet and a screw. The result is shown in Figure 338.

* *

Ref. 582 The magnetic field of the Earth has a dipole strength of $7.8 \cdot 10^{22}$ A m^2. It shields us, to-

gether with the atmosphere, from lethal solar winds and cosmic radiation particles, by deflecting them to the poles. Today, a lack of magnetic field would lead to high radiation on sunny days; but in the past, its lack would have prevented the evolution of the human species. We owe our existence to the magnetic field.

* *

The ionosphere around the Earth has a resonant frequency of 7 Hz; for this reason any apparatus measuring low frequencies always gets a strong signal at this value. Can you
Challenge 1044 s give an explanation of the frequency?

* *

Challenge 1045 s The Sun is visible to the naked eye only up to a distance of 50 light years. Is this true?

* *

At home, electricity is mostly used as alternating current. In other words, no electrons actually flow through cables; as the drift speed of electrons in copper wires is of the order

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

Page 773 of 1 µm/s, electrons just move back and forward by 20 nm. Nothing flows in or out of the cables! Why do the electricity companies require a real flow of money in return, instead Challenge 1046 e of being satisfied with a back and forth motion of money?

* *

Comparing electricity with water is a good way of understanding electronics. Figure 339 shows a few examples that even a teenager can use. Can you fill in the correspondence Challenge 1047 s for the coil, and thus for a transformer?

* *

Do electrons and protons have the same charge? Experiments show that the values are Challenge 1048 ny equal to within at least twenty digits. How would you check this?

* *

Challenge 1049 ny Charge is also velocity-independent. How would you check this?

* *

Magnets can be used, even by school children, to climb steel walls. Have a look at the www.physicslessons.com/TPNN.htm website.

* *

Extremely high magnetic fields have strange effects. At fields of 10^{10} T, vacuum becomes Page 728 effectively birefringent, photons can split and coalesce, and atoms get squeezed. Hydrogen atoms, for example, are estimated to get two hundred times narrower in one direction. Fortunately, these conditions exist only in specific neutron stars, called *magnetars*.

* *

A good way to make money is to produce electricity and sell it. In 1964, a completely new method was invented by Fletcher Osterle. The method was presented to a larger public in Ref. 583 a beautiful experiment in 2003. One can take a plate of glass, add a conducting layers on each side, and then etch a few hundred thousand tiny channels through the plate, each around 15 µm in diameter. When water is made to flow through the channels, a current is generated. The contacts at the two conducting plates can be used like battery contacts.

This simple device uses the effect that glass, like most insulators, is covered with a charged layer when it is immersed in a liquid. Can you imagine why a current is gener- Challenge 1050 s ated? Unfortunately, the efficiency of electricity generation is only about 1%, making the method much less interesting than a simple blade wheel powering a dynamo.

* *

For beautiful animations about magnetic and electric fields, see the website web.mit.edu/8.02t/www/802TEAL3D/visualizations.

* *

Gallium arsenide semiconductors can be patterned with so-called quantum dots and *point contacts*. These structures allow one to count single electrons. This is routinely done in several laboratories around the world.

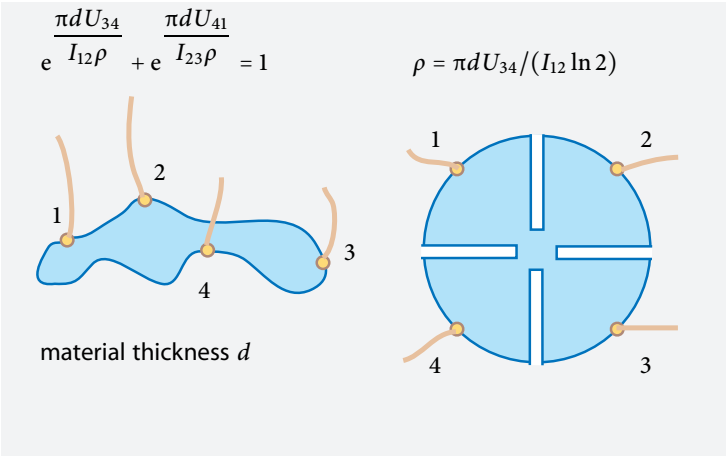

FIGURE 340 Can you deduce Van der Pauw's formula for the specific resistance of homogeneous layers of any shape (left) or its special case for a symmetrical shape (right)?

* *

Ohm's 'law', the observation that for almost all materials the current is proportional to the voltage, is due to a school teacher. Georg Simon Ohm* explored the question in great depth; in those days, such measurements were difficult to perform. This has changed now. Recently, even the electrical resistance of single atoms has been measured: in the case of xenon it turned out to be about $10^5\ \Omega$. It was also found that lead atoms are ten times more conductive than gold atoms. Can you imagine why?

Ref. 646

Challenge 1051 ny

* *

Ohm's 'law', so simple it seems, has many fascinating mathematical aspects. For example, in 1958, the Dutch physicist J.L. van der Pauw proved an astonishing formula and method that allows to measure the specific resistance ρ of material layers of *any* shape. One only needs to attach four gold wires to the layer anywhere on its border. The specific resistance is then given by the expression shown in Figure 340. Can you imagine how the formula is deduced? (This is not an easy problem.) The formula reduced the workload in laboratories across the world by a significant amount; before the formula had been discovered, in every experiment, researchers also had to produce separate samples that allowed to measure the specific resistance of the material they were investigating.

Challenge 1052 ny

* *

Ref. 647

The charges on two capacitors in series are not generally equal, as naive theory states. For perfect, leak-free capacitors the voltage ratio is given by the inverse capacity ratio $V_1/V_2 = C_2/C_1$, due to the equality of the electric charges stored. This is easily deduced from Figure 341. However, in practice this is only correct for times between a few and a few dozen minutes. Why?

Challenge 1053 s

* Georg Simon Ohm (b. 1789 Erlangen, d. 1854 München), Bavarian school teacher and physicist. His efforts were recognized only late in his life, and he eventually was promoted to professor at the University in München. Later the unit of *electrical resistance*, the proportionality factor between voltage and current, was named after him.

On certain high voltage cables leading across the landscape, small neon lamps shine when the current flows, as shown in Figure 342. (You can see them from the train when riding from Paris to the Roissy airport.) How is this possible?

Challenge 1054 ny

* *

Electric polarizability is the property of matter responsible for the deviation of water flowing from a tap caused by a charged comb. It is defined as the strength of electric dipole induced by an applied electric field. The definition simply translates the observation that many objects acquire a charge when an electric field is applied. Incidentally, how precisely combs get charged when rubbed, a phenomenon called *electrification*, is still one of the mysteries of modern science.

Page 670

* *

A pure magnetic field cannot be transformed into a pure electric field by change of observation frame. The best that can be achieved is a state similar to an equal mixture of magnetic and electric fields. Can you provide an argument elucidating this relation?

Challenge 1056 ny

Calculating resistance of infinite grids is one of the most captivating problems in electricity, as shown in Figure 343. Can you find the solution?

A SUMMARY: THREE BASIC FACTS ABOUT ELECTRICITY

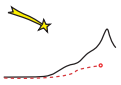
The experiments we have described so far show three basic connections:

- ▷ Electric charges exert forces on other charges.
- ▷ Electric charges are conserved.
- ▷ Charges, like all matter, move slower than light.

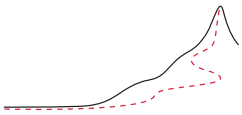
From these three statements – the definition of charge, the conservation of charge, and the invariance of the speed of light – we can deduce every aspect of classical electrodynamics. (If one wants, the non-existence of magnetic charge can be taken as an additional assumption.) In particular, Maxwell's field equations of electrodynamics can be deduced from these three statements. The field equations describe the way that charges *produce* any electric, magnetic or electromagnetic field.

Ref. 578 Ref. 579

The proof of the connection between charge conservation and the field equations can be given mathematically; we do not present it here, because the algebra is somewhat involved. The essential connection is that all of electrodynamics follows from the properties of charges that we have discovered so far.



Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009



Chapter 24

THE DESCRIPTION OF ELECTROMAGNETIC FIELD EVOLUTION

In the years between 1861 and 1865, taking in the details of all the experiments known to him, James Clerk Maxwell produced a description of electromagnetism that forms one of the pillars of physics.* Maxwell took all the experimental results and extracted their common basic principles, as shown in Figures 344 and 345. Twenty years later, Heaviside and Hertz extracted the main points of Maxwell ideas, calling their summary *Maxwell's theory of the electromagnetic field*. Maxwell's equations are evolution equations of the electromagnetic field. In the relativistic description, the set consists of *two* equations (four in the non-relativistic case).

Page 883

The first equation is the precise statement that electromagnetic fields *originate at charges*, and nowhere else. The first of Maxwell's equations for electrodynamics can variously be written**

$$d\boldsymbol{F} = j\mu_0 \quad \text{or}$$

$$d_\mu \boldsymbol{F}^{\mu\nu} = j^\nu \mu_0 = (\rho c, \boldsymbol{j})\mu_0 = (\rho_0 \gamma c, \rho_0 \gamma \boldsymbol{v})\mu_0 \quad \text{or}$$

$$(\partial_t/c, \partial_x, \partial_y, \partial_z) \begin{pmatrix} 0 & -E_x/c & -E_y/c & -E_z/c \\ E_x/c & 0 & -B_z & B_y \\ E_y/c & B_z & 0 & -B_x \\ E_z/c & -B_y & B_x & 0 \end{pmatrix} = \mu_0(\rho c, \boldsymbol{j}) \text{ or}$$

$$\nabla \cdot \boldsymbol{E} = \frac{\rho}{\varepsilon_0} \quad \text{and} \quad \nabla \times \boldsymbol{B} - \frac{1}{c^2}\frac{\partial \boldsymbol{E}}{\partial t} = \mu_0 \boldsymbol{j} \,. \tag{441}$$

(442)

Each of these four equivalent ways to write the equation makes a simple statement: *electrical charges carry the electromagnetic field*; they carry it along with them.

* James Clerk Maxwell (b. 1831 Edinburgh, d. 1879 Cambridge), Scottish physicist. He founded electromagnetism by theoretically unifying electricity and magnetism, as described in this chapter. His work on thermodynamics forms the second pillar of his activity. In addition, he studied the theory of colours and developed the colour triangle; he was one of the first people to make a colour photograph. He is regarded by many as the greatest physicist ever. Both 'Clerk' and 'Maxwell' were his family names.

** There is a certain freedom in writing the equations, because different authors absorb different combinations of the constants c and μ_0 into the definitions of the quantities F, A and j.

The equations can be generalized to cases where the charges are not surrounded by vacuum, but located inside matter. We will not explore these situations in our walk because, as we will see during our mountain ascent, the apparently special case of vacuum in fact describes all of nature.

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

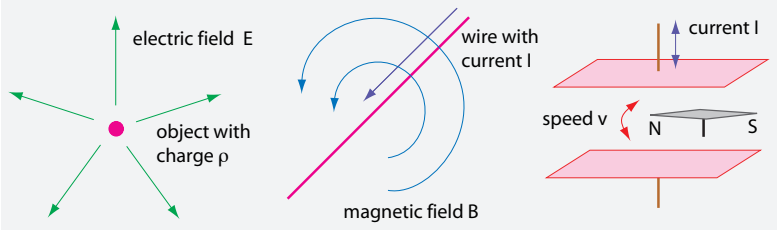


FIGURE 344 The first of Maxwell's equations

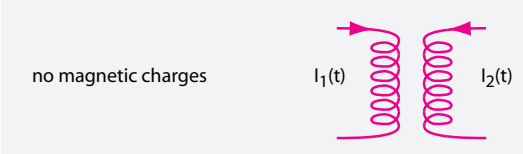

FIGURE 345 The second of Maxwell's equations

In other words, if one knows how charges move, one can determine the electromagnetic field $\boldsymbol{F}$. Static charges, described by a density ρ, produce electrostatic fields, and moving charges, described by a 3-current density $\boldsymbol{j}$, produce a mix of electric and magnetic fields.

This first equation is equivalent to the three basic observations of Figure 344: it describes Coulomb's relation, Ampère's relation, and the way changing electrical fields induce magnetic effects, as you may want to check for yourself.

Challenge 1057 ny

The first equation also contains the right hand rule for magnetic fields around wires, through the vector product. The equation also states, most clearly in its last form, that changing electric fields induce magnetic fields. Due to the vector product, all induced magnetic field lines are closed lines. The effect is essential in the primary side of transformers. The factor $1/c^2$ implies that the effect is small; that is why coils with many windings or strong electric currents are needed to produce or detect the effect.

Challenge 1058 e

The second of Maxwell's equations expresses the observation that in nature there are no magnetic charges, i.e., that magnetic fields have no sources. As a result, the equation also gives a precise description of how changing magnetic fields create electric fields, and vice versa. The second of Maxwell's equations for electrodynamics can variously be

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

written

$$
\begin{aligned}
& d\,{}^*\boldsymbol{F} = 0 \quad \text{with} \quad {}^*\boldsymbol{F}^{\rho\sigma} = \frac{1}{2}\varepsilon^{\rho\sigma\mu\nu}\boldsymbol{F}_{\mu\nu} \quad \text{or} \\
& d_\mu {}^*\boldsymbol{F}^{\mu\nu} = 0 \quad \text{or} \\
& (\partial_t/c, \partial_x, \partial_y, \partial_z)\begin{pmatrix} 0 & -B_x & -B_y & -B_z \\ B_x & 0 & E_z/c & -E_y/c \\ B_y & -E_z/c & 0 & E_x/c \\ B_z & E_y/c & -E_x/c & 0 \end{pmatrix} = (0,0,0,0) \quad \text{or} \\
& \varepsilon^{\sigma\mu\nu\rho}\partial_\mu \boldsymbol{F}_{\nu\rho} = 0 \quad \text{or} \\
& \partial_\mu \boldsymbol{F}_{\nu\rho} + \partial_\nu \boldsymbol{F}_{\rho\mu} + \partial_\rho \boldsymbol{F}_{\mu\nu} = 0 \quad \text{or} \\
& \nabla\cdot\boldsymbol{B} = 0 \quad \text{and} \quad \nabla\times\boldsymbol{E} = -\frac{\partial \boldsymbol{B}}{\partial t}\,. \qquad (443)
\end{aligned}
$$

The relation expresses the *lack of sources for the dual field tensor* ${}^*\boldsymbol{F}$; in other words, in nature there are no magnetic charges, i.e., no magnetic monopoles and no sources for magnetic fields. The equation thus tells in complex terms that cutting a magnet with a north and a south pole in any way always produces pieces with *two* poles, never a piece with a single pole.

Since there are no magnetic charges, magnetic field lines are always closed; they never start or end. For example, field lines continue inside magnets. This is often expressed mathematically by stating that the *magnetic flux* through a *closed* surface S – such as a sphere or a cube – *always vanishes*: $\int_S \boldsymbol{B}\mathbf{d}A = 0$.

The second half in the last formulation of equation (443) is shown schematically in Figure 345. It expresses that changes in magnetic fields produce electric fields: this effect is used in the secondary side of transformers and in dynamos. The cross product in the expression implies that an electric field generated in this way – also called an *electromotive field* – has no start and end points. The electromotive field lines thus run in circles: in most practical cases they run along electric circuits. In short, an electric field can have vortices only when there is a changing magnetic field. The minus sign is essential to ensure energy conservation and has a special name: it is called *Lenz's rule*.

In practice, the second Maxwell equation is always needed together with the first. Can you see why? Challenge 1059 ny

We note that the dual tensor ${}^*\boldsymbol{F}$ follows form the field tensor F by substituting E/c by B and B by E/c. This is the so-called *duality transformation*.

Together with Lorentz' evolution equation (436), which describes how charges move given the motion of the fields, Maxwell's evolution equations (441) and (443) describe *all* electromagnetic phenomena occurring on everyday scales, from mobile phones, car batteries, to personal computers, lasers, lightning, holograms and rainbows. We now have a description of electromagnetic fields as organized as the expression $a = GM/r$ or as Einstein's field equations for gravitation.

Maxwell's equations seem very complex. But we should never forget that they contain only four basic ideas: first: electric charges follow Coulomb's rule, second: electric charges moves slower than light, third: electric charges are conserved, and fourth: magnetic charges do not exist. If one wants to be very simplistic, Maxwell's equations are the

Motion Mountain – The Adventure of Physics available free of charge at www.motionmountain.eu Copyright © Christoph Schiller November 1997–January 2009

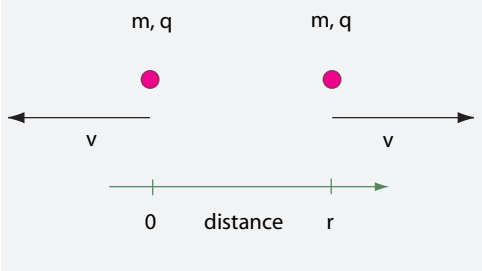

FIGURE 346 Charged particles after a collision

relativistic formulation of Coulomb's rule.

We will not study many applications of the field equations but will continue directly towards our aim to understand the connection between electromagnetic fields, everyday motion and the motion of light. In fact, the electromagnetic field has an important property that we mentioned right at the start: the field itself can move.

Colliding charged particles

A simple experiment clarifies the properties of electromagnetic fields defined above. When two charged particles collide, their total momentum is *not* conserved.

Imagine two particles of identical mass and identical charge just after a collision, when they are moving away from one another. Imagine also that the two masses are large, so that the acceleration due to their electrical repulsion is small. For an observer at the centre of gravity of the two, each particle feels an acceleration from the electric field of the other. The electric field E is given by the so-called *Heaviside formula*

Challenge 1060 ny

$$E = \frac{q(1 - v^2/c^2)}{4\pi e_0 r^2} \,. \tag{444}$$

In other words, the total system has a vanishing total momentum.

Take a second observer, moving with respect to the first with velocity v, so that the first charge will be at rest. Expression (444) leads to two *different* values for the electric fields, one at the position of each particle. In other words, the system of the two particles is not in inertial motion, as we would expect; the total momentum is not conserved. Where did it go?

Ref. 584

Challenge 1061 s

This at first surprising effect has been put in the form of a theorem by Van Dam and Wigner. They showed that for a system of particles interacting at a distance the total particle energy–momentum cannot remain constant in all inertial frames.

Ref. 585
